Preface to the third edition **xv**
Preface to the second edition **xvii**
Preface to the first edition **xix**
Contributors **xxi**

PART 1 GENERAL **1**

1 Embryology of malformations 3
Dietrich Kluth, Wolfgang Lambrecht, Christoph Bührer, and Roman Metzger
2 Transition to extrauterine life 17
Carlos E. Blanco and Eduardo Villamor
3 Clinical anatomy of the newborn 28
Mark D. Stringer and S. Ali Mirjalili
4 The epidemiology of birth defects 40
Edwin C. Jesudason
5 Prenatal diagnosis of surgical conditions 47
N. Scott Adzick
6 Fetal counseling for surgical malformations 63
Kokila Lakhoo
7 Fetal and birth trauma 72
Prem Puri and Piotr Hajduk
8 Transport of the surgical neonate 85
Prem Puri and Julia Zimmer
9 Specific risks for the preterm infant 93
Emily A. Kieran and Colm P. F. O'Donnell
10 Preoperative assessment 100
John Gillick, Dawn Deacy, and Prem Puri
11 Anesthesia 115
Nicholas Eustace and Kay O'Brien
12 Postoperative management of the surgical neonate 125
Suzanne Crowe
13 Fluid and electrolyte balance in the newborn 136
Judith Meehan, Joseph Chukwu, Winifred A. Gorman, and Eleanor J. Molloy
14 Nutrition 150
Simon Eaton and Agostino Pierro
15 Access for enteral nutrition 160
Michael W. L. Gauderer and Julia Zimmer
16 Stomas of small and large intestine 174
Andrea Bischoff and Alberto Peña
17 Vascular access in the newborn 180
Beth A. Rymeski and Frederick C. Ryckman

18 Radiology in the newborn 188
J. Kelleher, Ian H. W. Robinson, and Roisin Hayes
19 Immune system of the newborn 199
Judith Meehan, Murwan Omer, Fiona O'Hare, Denis J. Reen, and Eleanor J. Molloy
20 Neonatal sepsis 217
Jamie Golden, Jessica A. Zagory, Christopher P. Gayer, Tracy C. Grikscheit, and Henri R. Ford
21 Hematological problems in the neonate 233
Andrea M. Malone and Owen P. Smith
22 Genetics in neonatal surgical practice 245
Andrew Green
23 Ethical considerations in newborn surgery 261
Donna A. Caniano and Jacqueline J. Glover
24 Patient safety 271
Iain Yardley
25 Minimally invasive neonatal surgery 282
Richard Keijzer, Oliver J. Muensterer, and Keith E. Georgeson
26 Fetal surgery 292
Hanmin Lee and Benjamin Padilla
27 Tissue engineering and stem cell research 301
Paolo de Coppi
28 Surgical aspects of HIV infection 315
Alastair J. W. Millar, Brian Eley, and Sharon Cox
29 Liver transplantation 324
Alastair J. W. Millar and CWN Spearman

PART 2 HEAD AND NECK 335

30 Choanal atresia 337
Mira Sadadcharam and John D. Russell
31 Pierre Robin sequence 342
Udo Rolle, Aranka Ifert, and Robert Sader
32 Macroglossia 349
Thambipillai Sri Paran and George G. Youngson
33 Tracheostomy in infants 352
Jeyanthi Kulasegarah, Thom Lobe, and John D. Russell
34 Congenital cysts and sinuses of the neck 362
Yousef El-Gohary, Joseph Fusco, and George K. Gittes
35 Stridor in infants 372
Sam J. Daniel and Faisal Zawawi

PART 3 CHEST 381

36 Congenital thoracic deformities 383
Konstantinos Papadakis and Robert C. Shamberger
37 Mediastinal masses in the newborn 392
Israel Fernandez-Pineda and Stephen J. Shochat
38 Congenital airway malformations 398
Alessandro de Alarcón and Richard G. Azizkhan
39 Vascular rings 412
Benjamin O. Bierbach, John Mark Redmond, and Christopher Hart
40 Pulmonary air leaks 425
Prem Puri and Jens Dingemann
41 Chylothorax and other pleural effusions in neonates 431
Miho Watanabe, Belinda Hsi Dickie, and Richard G. Azizkhan
42 Congenital malformations of the lung 440
Shannon M. Koehler and Keith T. Oldham

43 Congenital diaphragmatic hernia 456
Prem Puri and Julia Zimmer
44 Extracorporeal life support for neonatal cardiorespiratory failure 468
William Middlesworth, Jeffrey W. Gander, and Charles J. H. Stolar
45 Bronchoscopy in the newborn 482
Mira Sadadcharam, Rohit Umesh Verma, and John D. Russell

PART 4 ESOPHAGUS 489

46 Esophageal atresia and tracheo-esophageal fistula 491
Paul D. Losty
47 Congenital esophageal stenosis 507
Masaki Nio, Motoshi Wada, and Hideyuki Sasaki
48 Esophageal duplication cysts 513
Dakshesh H. Parikh and Michael Singh
49 Esophageal perforation in the newborn 519
David S. Foley
50 Gastroesophageal reflux in the neonate and small infant 524
Michael E. Höllwarth

PART 5 GASTROINTESTINAL 535

51 Pyloric atresia and prepyloric antral diaphragm 537
Alessio Pini Prato, Vincenzo Jasonni, and Girolamo Mattioli
52 Infantile hypertrophic pyloric stenosis 543
Prem Puri, Balazs Kutasy, and Ganapathy Lakshmanadass
53 Gastric volvulus 558
Alan E. Mortell and Brendan R. O'Connor
54 Gastric perforation 565
Adam C. Alder and Robert K. Minkes
55 Duodenal obstruction 571
Yechiel Sweed and Alon Yulevich
56 Intestinal malrotation 588
Augusto Zani and Agostino Pierro
57 Congenital hyperinsulinism 591
Paul R. V. Johnson
58 Jejunoileal atresia and stenosis 597
Alastair J. W. Millar, Alp Numanoglu, and Sharon Cox
59 Colonic and rectal atresias 610
Tomas Wester
60 Meconium ileus 618
Guido Ciprandi and Massimo Rivosecchi
61 Meconium peritonitis 624
Jose L. Peiró and Jose Boix-Ochoa
62 Duplications of the alimentary tract 631
Prem Puri, Alan E. Mortell, and Farhan Tareen
63 Mesenteric and omental cysts 642
Benno Ure and Christoph Zoeller
64 Neonatal ascites 648
Prem Puri and Elke Ruttenstock
65 Necrotizing enterocolitis 653
Stephanie C. Papillon, Scott S. Short, and Henri R. Ford
66 Spontaneous intestinal perforation 660
Mark D. Stringer
67 Hirschsprung's disease 667
Prem Puri and Christian Tomuschat

68 Anorectal anomalies 684
Andrea Bischoff and Alberto Peña
69 Congenital pouch colon 701
Amulya K. Saxena and Praveen Mathur
70 Congenital segmental dilatation of the intestine 710
Yoshiaki Takahashi, Yoshinori Hamada, and Tomoaki Taguchi
71 Intussusception 714
Spencer W. Beasley
72 Inguinal hernia 719
Thambipillai Sri Paran and Prem Puri
73 Short bowel syndrome and surgical techniques for the baby with short intestines 727
Michael E. Höllwarth
74 Megacystis microcolon intestinal hypoperistalsis syndrome 737
Prem Puri and Jan-Hendrik Gosemann

PART 6 LIVER AND BILIARY TRACT 745

75 Biliary atresia 747
Mark Davenport
76 Congenital biliary dilatation 761
Hiroyuki Koga and Atsuyuki Yamataka
77 Hepatic cysts and abscesses 772
Jonathan P. Roach, David A. Partrick, and Frederick M. Karrer

PART 7 ANTERIOR ABDOMINAL WALL DEFECTS 779

78 Omphalocele and gastroschisis 781
Steven W. Bruch and Jacob C. Langer
79 Omphalomesenteric duct remnants 791
Kenneth K. Y. Wong and Paul K. H. Tam
80 Bladder exstrophy: Considerations and management of the newborn patient 795
Peter P. Stuhldreher and John P. Gearhart
81 Cloacal exstrophy 805
Alonso Carrasco Jr., Duncan T. Wilcox, and Vijaya M. Vemulakonda
82 Prune belly syndrome 813
Salvatore Cascio, Hideshi Miyakita, and Prem Puri
83 Conjoined twins 821
Juan A. Tovar and Leopoldo Martinez

PART 8 TUMORS 831

84 Epidemiology and genetic associations of neonatal tumors 833
Sam W. Moore
85 Hemangiomas and vascular malformations 849
Belinda Hsi Dickie, Arin K. Greene, and Steven J. Fishman
86 Congenital nevi 865
Lee W. T. Alkureishi and Bruce S. Bauer
87 Lymphatic malformations 882
Emily R. Christison-Lagay and Jacob C. Langer
88 Cervical teratomas 894
Michael W. L. Gauderer
89 Sacrococcygeal teratoma 899
Kevin C. Pringle
90 Nasal tumors 911
Udo Rolle

91 Neuroblastoma 918
Andrew M. Davidoff
92 Soft-tissue sarcoma 930
Martin T. Corbally
93 Hepatic tumors 935
Benjamin A. Farber, William J. Hammond, and Michael P. La Quaglia
94 Congenital mesoblastic nephroma and Wilms tumor 958
Philip J. Hammond and Robert Carachi
95 Neonatal ovarian masses 963
Rachael L. Polis, Mary E. Fallat, and Chad Wiesenauer

PART 9 SPINA BIFIDA AND HYDROCEPHALUS 973

96 Spina bifida and encephalocele 975
Jothy Kandasamy, Mark A. Hughes, and Conor L. Mallucci
97 Hydrocephalus 988
Jothy Kandasamy, Maggie K. Lee, Mark A. Hughes, and Conor L. Mallucci

PART 10 GENITOURINARY 999

98 Urinary tract infections 1001
Martin Koyle
99 Imaging of the renal tract in the neonate 1010
Melanie Hiorns and Lorenzo Biassoni
100 Management of antenatal hydronephrosis 1029
Jack S. Elder
101 Multicystic dysplastic kidney 1048
David F. M. Thomas and Azad S. Najmaldin
102 Upper urinary tract obstructions 1057
Prem Puri and Boris Chertin
103 Ureteral duplication anomalies 1072
Prem Puri and Hideshi Miyakita
104 Vesicoureteral reflux 1079
Prem Puri and Manuela Hunziker
105 Ureteroceles in the newborn 1088
Jonathan F. Kalisvaart and Andrew J. Kirsch
106 Posterior urethral valves 1099
Paolo Caione and Michele Innocenzi
107 Neurogenic bladder in the neonate 1116
Salvatore Cascio and Malcolm A. Lewis
108 Hydrometrocolpos 1124
Devendra K. Gupta and Shilpa Sharma
109 Disorders of sexual development 1132
Maria Marcela Bailez
110 Male genital anomalies 1147
John M. Hutson
111 Neonatal testicular torsion 1154
David M. Burge and Jonathan Durell

PART 11 LONG-TERM OUTCOMES IN NEWBORN SURGERY 1157

112 Long-term outcomes in newborn surgery 1159
Christian Tomuschat, Keith T. Oldham, and Casey M. Calkins

Index 1185

Preface to the fourth edition

Newborn surgery has reached a high degree of sophistication and is now recognized as an independent discipline in pediatric surgery. The more comprehensive understanding of the pathophysiology of various neonatal disorders, advances in specialized neonatal anesthesia and intensive care, as well as the introduction of new surgical techniques including minimally invasive surgery have dramatically improved survival in neonatal surgical conditions. Recent advances in the fields of regenerative medicine and tissue engineering offer hope in the future to provide stem cell–based constructs for the reconstruction of some birth defects.

It has been six years since the third edition of the book (published in 2011). The fourth edition of *Newborn Surgery* has been thoroughly revised and updated, and contains 112 chapters by 194 contributors from five continents. This edition contains nine new chapters on key topics, including transition to extrauterine life, specific risks for the preterm infant, access for enteral nutrition, patient safety, tissue engineering and stem cell research, surgical aspects of HIV infection, stridor in infants, stomas of small and large intestine, and spontaneous intestinal perforation. Each chapter has been written by internationally renowned leaders in their respective fields. Several younger surgeons were selected as coauthors, who will become the next generation of leaders in pediatric surgery.

This book is intended for those who have a clinical responsibility for newborn babies. It provides an authoritative, comprehensive, and complete account of the pathophysiology and surgical management of neonatal disorders. The book is specifically designed for pediatric surgeons, trainees in pediatric surgery, pediatric urologists, as well as neonatologists and pediatricians seeking more detailed information on newborn surgical conditions. It is my sincere hope that the readers will find this textbook a useful reference in the management of surgical disorders in the newborn.

I wish to thank most sincerely all the contributors from around the world for their precious time and outstanding work in the preparation of this innovative textbook. I also wish to express my gratitude to Dr. Julia Zimmer and Dr. Hiroki Nakamura for their help with the galley proofs of the book. I wish to thank the editorial staff of CRC Press, particularly Ms. Miranda Bromage, for all their help during the preparation and publication of this book. I am thankful to the National Children's Research Centre, Our Lady's Children's Hospital, Dublin for their support.

Preface to the third edition

It has been eight years since the second edition of the book was published in 2003. Over the last decade, major advances have occurred in the understanding and treatment of neonatal surgical conditions. Advances in prenatal diagnosis, imaging, intensive care, and minimally invasive surgery have transformed the practice of surgery in the newborn. The third edition of *Newborn Surgery* has been extensively revised and contains 105 chapters by 160 contributors from five continents of the world. This edition contains many new chapters taking account of the recent advances in neonatal surgery. The new chapters include the following: Perinatal Physiology; Clinical Anatomy of the Newborn; Epidemiology of Birth Defects; Fetal Counselling for Surgical Malformations; Neonatal Sepsis; Liver Transplantation; Congenital Pouch Colon; Megacystis Microcolon Intestinal Hypoperistalsis Syndrome; and Urinary Tract Infections. Each chapter has been written by world-class experts in their respective fields, along with their coauthors.

This textbook provides an authoritative, comprehensive, and complete account of the pathophysiology and treatment of various surgical conditions in the newborn. This book should be of interest to all those who have a clinical responsibility for newborn babies. It is particularly intended for trainees in pediatric surgery, established pediatric surgeons, general surgeons with an interest in pediatric surgery, as well as neonatologists and pediatricians seeking more detailed information on newborn surgical conditions.

I wish to thank most sincerely all the contributors for their outstanding work in producing this innovative textbook. I also wish to express my gratitude to Ms. Vanessa Woods and Ms. Lisa Kelly for their skillful secretarial help. I am grateful to Dr. G.P. Seth for reading each and every word of the galley proofs of the entire book. I wish to thank the editorial staff of Hodder Arnold, particularly Mr. Stephen Clausard, for their help during the preparation and publication of this book. I am thankful to the Children's Medical & Research Foundation, Our Lady's Children's Hospital, Dublin for their support.

Preface to the second edition

The second edition of *Newborn Surgery* has been extensively revised. Many new chapters have been added to take account of the recent developments in the care of the newborn with congenital malformations. This edition, which comprises 97 chapters by 121 contributors from five continents of the world, provides an authoritative, comprehensive, and complete account of the various surgical conditions in the newborn. Each chapter is written by the current leading expert(s) in their respective fields.

Newborn surgery in the twenty-first century demands of its practitioners detailed knowledge and understanding of the complexities of congenital anomalies, as well as the highest standards of operative techniques. In this textbook, great emphasis continues to be placed on providing a comprehensive description of operative techniques of each individual congenital condition in the newborn. The book is intended for trainees in pediatric surgery, established pediatric surgeons, general surgeons with an interest in pediatric surgery, as well as neonatologists and pediatricians seeking more detailed information on newborn surgical conditions.

I wish to thank most sincerely all the contributors for the outstanding work they have done for the production of this innovative textbook. I also wish to express my gratitude to Mrs. Karen Alfred and Ms. Ann Brennan for their secretarial help and to the staff of Hodder Arnold for their help during the preparation and publication of this book. I am grateful to the Children's Medical & Research Foundation, Our Lady's Hospital for Sick Children, Dublin for their support.

Preface to the first edition

During the last three decades, newborn surgery has developed from an obscure subspecialty to an essential component of every major academic pediatric surgical department throughout both the developed and the developing world. Major advances in perinatal diagnosis, imaging, neonatal resuscitation, intensive care, and operative techniques have radically altered the management of newborns with congenital malformations. Embryological studies have provided new valuable insights into the development of malformations, while improvements in prenatal diagnosis are having a significant impact on approaches to management. Monitoring techniques for the sick neonate pre- and postoperatively have become more sophisticated, and there is now greater emphasis on physiological aspects of the surgical newborn, as well as their nutritional and immune status. This book provides a comprehensive compendium of all these aspects as a prelude to an extensive description of surgical conditions in the newborn. Modern-day newborn surgery demands detailed knowledge of the complexities of newborn problems. Research developments, laboratory diagnosis, imaging, and innovative surgical techniques are all part of the challenge facing surgeons dealing with congenital conditions in the newborn. In this book, a comprehensive description of operative techniques of each individual condition is presented. Each of the contributors was selected to provide an authoritative, comprehensive, and complete account of their respective topics. The book, comprising 90 chapters, is intended primarily for trainees in pediatric surgery, established pediatric surgeons, general surgeons with an interest in pediatric surgery, and neonatologists.

I am most grateful to all contributors for their willingness to contribute chapters at considerable cost of time and effort. I am indebted to Mr. Maurice De Cogan for artwork, Mr. Dave Cullen for photography, and Ms. Ann Brennan and Ms. Deirdre O'Driscoll for skillfull secretarial help. I am grateful to the Children's Research Centre, Our Lady's Hospital for Sick Children, for their support. Finally, I wish to thank the editorial staff, particularly Ms. Susan Devlin, of Butterworth-Heinemann for their help during the preparation and publication of this book.

Embryology of malformations

DIETRICH KLUTH, WOLFGANG LAMBRECHT, CHRISTOPH BÜHRER, AND ROMAN METZGER

INTRODUCTION

Approximately 3% of human newborns present with congenital malformations.[1] Without surgical intervention, one-third of these infants would die since their malformations are not compatible with sustained life outside the uterus.[1,2] In figures, this means that in a country such as Germany, nearly 6000 children are born every year with a life-threatening malformation.

Due to the development of prenatal diagnostic procedures, advanced surgical techniques, and intensive postoperative care, most infants with otherwise fatal malformations can be rescued by an operation in the neonatal period. However, morbidity remains high in some of these children[2] with the necessity of repeated operations and hospitalizations despite a successful primary operation. This may also be the fate of many children with non-life-threatening malformations such as hypospadias or cleft palate.

Mortality is still high in newborns with certain malformations such as congenital diaphragmatic hernias (CDHs) or severe combined defects. As a consequence, congenital malformations today are the main cause of death in the neonatal period. In the United States, 21% of neonatal mortality can be related to congenital malformations.[3]

These figures probably do not reflect a real increase in the actual incidence of congenital malformations. The observed mortality shift might rather be due to improved intensive care medicine in today's Western world countries where neonates (even those with birth defects) have a better chance of survival. On the other hand, this statistical shift indicates that knowledge about congenital malformations lags behind the progress clinical research has made in the surrounding fields. Efforts are needed to close the gap and learn more about baby killer no. 1. Identification of teratogens will help to reduce the incidence of malformations when exposure can be avoided, and pathogenetic studies might aid in designing therapeutic measures. Both treatment and prevention critically depend on basic embryological research.

GENERAL REMARKS ON EMBRYOLOGY AND THE EMBRYOLOGY OF MALFORMATIONS

Despite many efforts, the embryology of numerous congenital anomalies in humans is still a matter of speculation. This is due to the following reasons:

1. A shortage of study material (both normal and abnormal embryos)
2. Various technical problems (difficulties in the interpretation of serial sections, shortage of explanatory three-dimensional reconstructions)
3. Misconceptions and/or outdated theories concerning normal and abnormal embryology

Fortunately, a number of animal models are known today, which allow advanced embryological studies in various embryological fields. Especially for the studies of anorectal malformations, a number of animal models are at hand. In addition, a scanning electron microscopic atlas of human embryos had been published recently, which provides detailed insights into normal human embryology.[4]

Appropriate and illustrative findings in various fields of embryology are still lacking. This explains why today many typical malformations are still not explained satisfactorily. Pediatric surgeons are still confused when they are confronted with the embryological background of normal and abnormal development.

For the described misconceptions and/or outdated theories, Haeckel's "biogenetic law"[5] is one example. According to this theory, a human embryo recapitulates in its individual development (ontogeny) the morphology observed in all life forms (phylogeny). This means that during its development, an advanced species is seen to pass through stages represented by adult organisms of more primitive species.[5]

This theory still has an impact on the nomenclature of embryonic organs and explains why human embryos have "cloacas" like adult birds and "branchial" clefts like adult fish.

Another very popular misconception is the theory that malformations actually represent "frozen" stages of normal embryology ("Hemmungsmißbildung").[6] As a result, our understanding of normal embryology stems more from pathological–anatomic interpretations of observed malformations than from proper embryological studies. The theory of the "rotation of the gut" as a step in normal development is a perfect example for this misconception.

DEFINITION OF THE TERM "MALFORMATION"

After birth, neonates can present with a broad spectrum of deviations from normal morphology. This extends from minor variations of normal morphology without any clinical significance to maximal organ defects with extreme functional deficits of the malformed organs or of the whole organism.

The degree of functional disorder is decisive when dealing with the question of whether a variation of normal morphology has to be viewed as a dangerous malformation requiring surgical correction. This means that functional disturbance is essential when using the term "malformation." Inborn deviations can be detrimental, neutral, or even beneficial; otherwise, evolutionary progress could not take place. An example of a beneficial deviation is the longevity syndrome of people with abnormally low serum cholesterol levels. Abnormalities with little or no functional disturbance might still require surgical correction when patients are in danger of social stigmatization. Coronal or glandular hypospadias might serve as an example for this condition.

ETIOLOGY OF CONGENITAL MALFORMATIONS

In most cases, the etiology of congenital malformations remains unclear. Possible etiological factors are listed in Table 1.1.

In about 20% of cases, genetic factors (gene mutation and chromosomal disorders) can be identified.[1,2,7] In 10%, an environmental origin can be demonstrated.[1,2] In 70%, the factors responsible remain obscure.

Environmental factors

A large number of agents are known that might interfere with the normal development of organ systems during embryogenesis.[1,7] The underlying mechanisms of this interference are poorly understood in most cases. Characteristically, during organogenesis, different organs of the embryo show distinct periods of greatest sensitivity to the action of the teratogen. These phases of greatest sensitivity are called the "teratogenetic period of determination."[8] The typical patterns of some syndromes can be explained by an overlap of these phases during embryological development.

Table 1.1 Etiology of congenital malformations

Genetic disorders	20%
Environmental factors	10%
Unknown etiology	70%

In 1983, Shepard[2] published a catalogue of suspected teratogenic agents. Over 900 agents are known to produce congenital anomalies in experimental animals. In 30 agents, evidence for teratogenic action in humans could be demonstrated. Teratogenic agents can be divided into four groups (Table 1.2).

The teratogenic potential of virus infections,[1] especially rubella and herpes, and that of radiation[1] has been clearly established. Maternal metabolic defects and lack of essential nutritives can be teratogenic. After a vitamin A–free diet[9] and riboflavin-free diet,[10] various congenital malformations were observed in rats and mice. Among these were diaphragmatic hernias, isolated esophageal atresias, and isolated tracheo-esophageal fistulas. Similarly, inappropriate administration of hormones can be associated with intrauterine dysplasias.[11]

Industrial and pharmaceutical chemicals such as tetrachlor-diphenyl-dioxin or thalidomide have inflicted tragedies by their teratogenic action. When thalidomide was prescribed to women in the early 1960s as a "safe" sleeping medication, numerous children were born with dysmelic deformities.[7,12,13] In addition, atresias of the esophagus, the duodenum, and the anus were observed in some children.[12] The data collected suggest that teratogenic agents do not cause new patterns of malformations but rather mimic sporadic birth defects. This had posed problems in identifying thalidomide as the responsible agent. It appears likely that among those 70% congenital malformations with unclear etiology, a considerable percentage might be precipitated by as yet unidentified environmental factors. In a rat model, the herbicide nitrofen (2,4-dichlorophenyl-p-nitrophenyl ether) has been shown to induce CDHs, cardiac abnormalities, and hydronephrosis.[14–18] In 1978, Thompson et al.[19] described the teratogenicity of the anticancer drug Adriamycin in rats and rabbits. More recently, Diez-Pardo et al.[20] re-described

Table 1.2 Teratogenic agents in congenital malformations

Physical agents (radiation, heat, mechanical factors)
Infectious agents (viruses, treponemes, parasites)
Chemicals and drugs (thalidomide, nitrofen)
Environmental agents (hormones, vitamin deficiencies)
Maternal, genetic, and chromosomal disorders
Multifactorial inheritance

Source: Nadler HL. Teratology. In: Welch KJ, Randolph JG, Ravitch MM, O'Neill JA, Rowe MJ (editors). *Pediatric Surgery*. 4th Edition. Chicago: Year Book Medical Publishers, 1986:11–3.

this model with emphasis to its potentials as a model for foregut anomalies. Today, the Adriamycin model is generally described as a model for the VACTERL association (V = vertebral, A = anorectal, C = cardiac, T = tracheal, E = esophageal, R = renal, L = limb).[21,22] Thus, classic malformations such as atresias of the esophagus and the intestinal tract, intestinal duplications, and others can be mimicked by teratogens in animal models.

Genetic factors

Approximately 20% of congenital malformations are of genetic origin. Most surgically correctable malformations are associated with chromosomal disorders, e.g., trisomy 21, 13, or 18, or are of multifactorial inheritance[23] with a small risk of recurrence. The assumption of multifactorial inheritance results from the fact that with nearly all major anomalies familiar occurrences had been observed.[1] In animals, inheritance has also been found for some malformations.[24–27]

EMBRYOLOGY AND ANIMAL MODELS

Over the last two decades, a number of animal models were developed with the potential to gain a better understanding of the morphology of not only malformed but also normal embryos. These animal models can be divided into four subgroups.

Surgical models

In the past, the chicken was an important surgical model to study embryological processes. Due to the easy access to the embryo, its broad availability, and its cheapness, the chicken is an ideal model for experimental studies. It has been widely used by embryologists especially in the field of epithelial/mesenchymal interactions.[28–30] Pediatric surgeons used this model to study morphological processes involved in intestinal atresia formation,[31,32] gastroschisis,[33] and M. Hirschsprung.[34]

The Czech embryologist Lemez[35] used chicken embryos in order to induce tracheal agenesis with tracheo-esophageal fistula.

Apart from these purely embryonic models, a large number of fetal models exist. However, these models were mainly used in order to demonstrate the feasibility of fetal interventions.[36]

Chemical models

A large number of chemicals can have an impact on the normal development of humans and animals alike. The following are the most important chemicals today: (1) Adriamycin,[19,20] (2) etretinate,[37,38] (3) all-trans retinoic acid (ATRA),[39–41] (4) ethylenethiourea,[42–44] and (5) nitrofen.[15,16,18]

While models 1 to 4 are used to study the embryology of atresias of the esophagus, the gut, and the anorectum, model 5 was developed to study the malformations of the diaphragm, the lungs, the heart, and kidneys (hydronephrosis).

Genetic models

A number of genetic models had been developed that had been used for embryological studies in the past. These animals can be the product of spontaneous mutations or are the result of genetic manipulations, mainly in mice (transgenic mice).

1. Models of spontaneous origin: the SD mouse model[25,27]
2. Inheritance models: the pig model of anal atresia[24,26]
3. "Knockout" models[45–47]

The number of transgenic animal models is growing fast. For pediatric surgeons, those models are of major importance, which result in abnormalities of the fore- and hindgut. Here, interference with the sonic hedgehog pathway has proven to be very effective.[45–47] There are two ways to interfere with that pathway:

1. Targeted deletion of sonic hedgehog (Shh)[45,46]
2. Deletion of one of the three transcription factors Gli1, Gli2, and Gli3[46,47]

In the foregut, targeted deletion of Shh causes esophageal atresia/stenosis, tracheo-esophageal fistulas, and tracheal/lung anomalies in homozygous Shh null mutant mice.[45] In the hindgut, the deletion of Shh caused the formation of "cloacas,"[46] while Gli2 mutant mice demonstrated the "classic" form of anorectal malformations and Gli3 mutants showed minor forms like anal stenosis.[46,47] Interestingly, the morphology of Gli2 mutant mice embryos resembles that of heterozygous SD-mice embryos, while Shh null mutant mice embryos had morphological similarities with homozygous SD-mice embryos. Interestingly, after administration of Adriamycin, changes in the normal pattern of Shh distribution in the developing foregut were demonstrated.[48]

Viral models

Animal models that use virus infections to produce malformations important for pediatric surgeons are very rare. One exception is the murine model of extra hepatic biliary atresia (EHBA). In this model, newborn Balb/c mice are infected with rhesus rotavirus group A.[49] As a result, the full spectrum of EHBA develops as it is seen in newborns with this disease. However, this model is not a model to mimic failed embryology. But it highlights the possibility that malformations are not caused by embryonic disorders but by fetal or even postnatal catastrophes.

This part on embryology and animal models further highlights the importance of the study of normal animal embryos. Today, much information in current textbooks on human embryology stems from studies done in animals of varied species. Many of these are outdated. However, the

wide use of transgenic mice in order to mimic congenital malformations makes morphological studies of the various organ systems in normal mice mandatory. Otherwise, the interpretation of the effects of the deletion of genetic information can be very difficult.[50]

EMBRYOLOGY OF MALFORMATIONS

Disturbances of normal embryological processes will result in malformations of organs. This was first shown by Spemann[51] in 1901 by experimentally producing supernumerary organs in the triton embryo after establishing close contact between excised parts of triton eggs and other parts of the same egg. Spemann and Mangold[5] coined the term "induction" to describe this observation. They found that certain parts of the embryo obviously were able to control embryonic development of other parts. These controlling parts were called "organizers."[5] The process of influence itself was called "induction."

It was believed by many scientists in the field that "induction" could serve as the overall principle of hierarchical control of embryonic development. Ensuing investigations, however, made modifications necessary, which finally resulted in a very complex model of organizers and inductors. The nature of inductive substances remained obscure, and attempts to isolate inductive substances, currently called "morphogenes," were unsuccessful.[52] Interestingly, not only live cells could induce development in certain experiments but also dead and denatured materials.[5]

A process essential for the formation of early embryonic organs is the invagination of epithelial sheets. This invagination is preceded by a thickening of the epithelial sheet,[53] a process known as placode formation. The thickening itself is caused by elongation of individual cells of the placode. This process can be studied in detail in epithelial morphogenesis.[54] The same sequence of developmental events has been observed in the formation of the neural plate, in the formation of the optic and lens placode, and in the development of most epitheliomesenchymal organs including the lung, the thyroid gland, and the pancreas. From these observations, it can be concluded that most epithelial cells behave uniformly in the early phase of embryonic development.

Today it is generally accepted that early embryonic organs are especially sensitive for alterations. Therefore, researchers are more and more interested to understand the formation of early embryonic organs.

In 1985, Ettersohn[55] stated that most invaginations are the result of mechanical forces that are local in origin. He focused on three possible mechanisms that might lead to placode formation and subsequent invagination:

1. Change of cell shape by cell adhesion
2. Microfilament-mediated change of cell shape
3. Cell growth and division

In the following part, we will discuss some aspects of these mechanisms.

A teratological method used to determine the function of cell adhesion molecules (CAMs) in vivo during embryogenesis has been reported recently.[56] Mouse hybridoma cells producing monoclonal antibodies against the avian integrin complex were grafted into 2- or 3-day-old chick embryos. Depending on the site of engraftment, local muscle agenesis was observed. This is an example that the immunologic immaturity of the embryo can be exploited to study the contribution of cell attachment molecules to organ development in a functional fashion. A number of monoclonal antibodies directed against cell attachment molecules of various species have become available over the last years, and the structure of the binding molecules has been elucidated biochemically and by cDNA cloning. Functionally, adhesion molecules may be grouped into three families: (1) CAMs, which mediate specific and mostly transient cell recognition of other cells; (2) substrate adhesion molecules (SAMs), necessary for attachment to extracellular matrix proteins; and (3) cell-junctional molecules (CJMs), found in tight and gap junctions. Whereas CJMs apparently play an important role for metabolic signaling within established tissues, CAMs and SAMs are necessary for the formation of histologically distinct structures and directed migration of single cells. Among CAMs and SAMs, at least three families have been identified biochemically: integrins,[57] members of the immunoglobulin superfamily, and LEC-CAMS.[58] Integrins are heterodimeric molecules consisting of a larger α chain, which is associated with a smaller β chain in a calcium-dependent way. Usually, one given α chain might be found in association with various chains, but promiscuity of β chains has been described recently. Functionally, members of the integrin family present as SAMs (adhesion to vitronectin, collagen, fibronectin, complement components, or other intercellular matrix proteins) or CAMs (direct adhesion to other cells via corresponding cell surface target molecules). For example, cells bearing the integrin LFA-1 on their cell surface bind to cells expressing ICAM-1 or ICAM-2, both of which are members of the immunoglobulin superfamily.[59,60] Other members of the immunoglobulin superfamily that are known to be important during morphogenesis include liver CAM[61] (L-CAM) and neural CAM[62,63] (N-CAM). Both show homophilic aggregation; that is, N-CAM serves as a target structure for N-CAM, and L-CAM serves as a target structure for L-CAM, but there is no cross-reactivity. In developing feather placodes in avian embryos, L-CAM and N-CAM are mutually exclusive expressed on epidermal or mesodermal cells, respectively. When the placodes are incubated with antibodies to L-CAM, primarily only epidermal cell-to-cell contact is disturbed.[64] However, the structure of the surrounding mesoderm is altered subsequently, suggesting an inductive signal loop between epidermal and mesodermal cells. A third group of adhesion molecules has been termed LEC-CAMs to indicate that their extracellular part consists of a lectin domain, an epidermal growth factor (EGF)-like domain, and a complement regulatory protein repeat domain. The lectin domain is presumed to contain the active center; binding mediated by the murine homolog

to the leukocyte adhesion molecule 1 (LAM-1)[65] can be blocked by mannose-6-phosphate or its polymers.[66] Lectin-dependent organ formation should be accessible experimentally by administration of the respective carbohydrates, but few, if any, data have been reported so far.

Cell shape is mainly maintained by microtubules forming the cellular cytoskeleton. In addition, contractile elements exist such as actin, which are essential for cell movement, the so-called microfilaments. These structures are thought to be essential for the process of placode formation and invagination.[67] Microfilament-mediated change of cell shape is based on the idea that actin filaments could alter the shape of cells by contraction. Most of these filaments are found at the apex of epithelial cells. Contraction of these filaments in each individual cell of a cell layer would result in an increasing infolding of the whole cell layer,[67,68] finally resulting in invagination. It is a disadvantage of this model, however, that there is no apparent reason why apical constriction should proceed by cell elongation.[55]

Cell proliferation is probably an essential factor in the morphogenesis of epitheliomesenchymal organs. During morphogenesis of these organs, repeated invagination can be observed, which might be dependent upon cell proliferation.[69] The way in which epithelial cell growth and proliferation is controlled in the embryo is not clear. However, it is believed that the surrounding mesenchyme might regulate the timing and location of invagination of the epithelial layer. Goldin and Opperman[28] proposed that EGF might be excreted by mesenchymal cells, which would stimulate epithelial cell proliferation and repeated invagination. When agarose pellets impregnated with EGF were cultured alongside 5-day embryonic chick tracheal epithelium, supernumerary buds were induced to form at those sites. EGF and the related peptide transforming growth factor-β (TGFβ) have been shown to lead to precocious eyelid opening when injected into newborn mice.[70] Thus, complex changes of late-stage organ development can be induced by physiological stimuli in the laboratory. Interestingly, EGF is a mitogen for many epithelial cells in vitro without affecting most mesenchymal cells. A large variety of cells have been demonstrated to display the receptor for EGF/TGFβ on their cell surface, which is encoded by the cellular proto-oncogene c-erbB. Structural alterations of this receptor are known to result in uncontrolled proliferation and ultimately malignant transformation. When secreted locally, EGF might provide physically associated cells with appropriate on and off signals required for the formation of complex organs. Other polypeptides, such as platelet-derived growth factor or transforming growth factor-α (TGFα), appear to function in an antagonistic way in that they stimulate rather the proliferation of mesenchymal cells.[71,72] In defined experimental situations, TGFα has been shown to be a mitogen for osteoblasts while being a potent inhibitor of the proliferation of epithelial and endothelial cells at the same time. Embryonic fibroblasts, however, are also inhibited by TGFα.[73] TGFα is a powerful chemotactic agent for fibroblasts and enhances the production of both collagen and fibronectin by these cells. There are, however, little data available concerning the involvement of these factors during normal and pathologic development of the embryo. Future investigations using such powerful approaches as in situ hybridization with cloned genes, preparation of transgenic animals, and direct administration of the recombinant proteins to various parts of the embryo might shed some light on signaling pathways mediated by soluble cytokines.

The surrounding mesenchyme might limit the expansion of the epithelial bud[74] forcing the epithelial sheet to fold in characteristic patterns. If a growing cell layer is restricted from lateral expansion, "mitotic pressure" by dividing cells will result in elongation of cells and then invagination of the "crowded" cell sheet. This does not necessarily imply that cells divide more rapidly in the region of invagination than in the surrounding areas. The main effect is caused by restriction of lateral expansion.[29,30] In the early anlage of the thymus, cell proliferation counts are actually lower in the thymus anlage than in the surrounding epithelium.[75] Steding[29] and Jacob[30] have shown experimentally that restriction of lateral expansion might be responsible for thickening and subsequent invagination of epithelial sheets. In their experiments, restriction of lateral expansion was caused by a tiny silver ring placed on the epithelium of chick embryos.

EXAMPLES OF PATHOLOGICAL EMBRYOLOGY

The focus of our research has been the embryology of foregut, anorectal, and diaphragmatic malformations. We studied the normal development of all embryonic organs involved by scanning electron microscopy (SEM).[76–82] In addition, we employed two rodent animal models to study malformations of the anorectum and the diaphragm. Pathogenetic concepts concerning these malformations were controversial in the past due to lack of detailed data.

EMBRYOLOGY OF FOREGUT MALFORMATIONS

The differentiation of the primitive foregut into the ventral trachea and dorsal esophagus is thought to be the result of a process of septation.[83] It is guessed that lateral ridges appear in the lateral walls of the foregut, which fuse in midline in a caudocranial direction, thus forming the tracheo-esophageal septum. This theory of septation has been described in detail by Rosenthal[84] and Smith.[85] However, others[86,87] were not able to verify the importance of the tracheo-esophageal septum for the differentiation of the foregut. They instead proposed individually that the respiratory tract develops simply by further growth of the lung bud in a caudal direction.

Using SEM, we studied the development of the foregut in chick embryos.[76,77] In this study, we were unable to demonstrate the formation of a tracheo-esophageal septum (Figure 1.1). A sequence of SEM photographs of staged chick embryos suggests that differentiation of the primitive

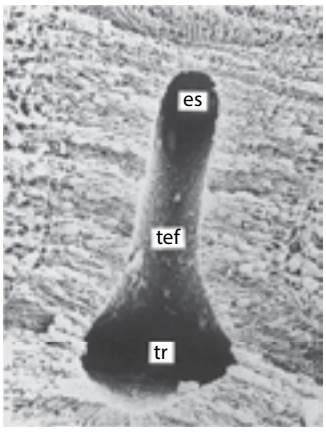

Figure 1.1 SEM photograph of the inner layer of foregut epithelium in a chick embryo (approx. 3.5 days old). View from cranial. Between trachea (tr) on bottom and esophagus (es) on top, the tip of the tracheo-esophageal fold (tef) is recognizable. Lateral ridges or signs of fusion are not found.

foregut is best explained by a process of "reduction of size" of a foregut region called the "tracheo-esophageal space" (Figure 1.2). This reduction is caused by a system of folds that develops in the primitive foregut. They approach each other but do not fuse (Figure 1.2).

Based on these observations, the development of the malformation can be explained by disorders either of the formation of the folds or of their developmental movements:

1. Atresia of the esophagus with fistula (Figure 1.3a): The dorsal fold of the foregut bends too far ventrally. As a result, the descent of the larynx is blocked. Therefore, the tracheo-esophageal space remains partly undivided and lies in a ventral position. Due to this ventral position, it differentiates into trachea.

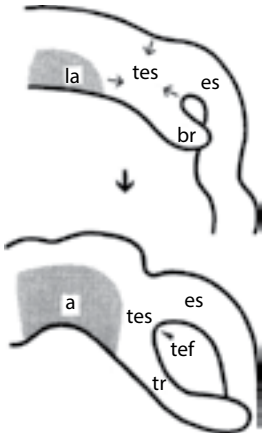

Figure 1.2 Summarizing sketch of foregut development. The tracheo-esophageal space (tes) is reduced in size by developmental movements of folds (indicated by arrows) (es, esophagus; la, anlage of larynx; br, bronchus; tr, trachea). Short arrow marks tip of tracheo-esophageal fold (tef) (compare Figure 1.1).

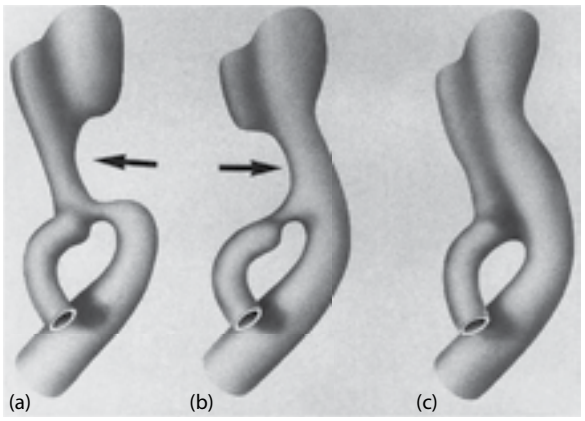

Figure 1.3 Sketch of formal pathogenesis of typical foregut malformations (see text for details): **(a)** atresia of esophagus with fistula; **(b)** atresia of trachea with fistula; **(c)** laryngotracheo-esophageal cleft. Arrows indicate sites of possible deformation of the developing foregut.

2. Atresia of the trachea with fistula (Figure 1.3b): The foregut is deformed on its ventral side. The developmental movements of the folds are disturbed, and the tracheo-esophageal space is dislocated in a dorsal direction. Therefore, it differentiates into esophagus.
3. Laryngotracheo-esophageal clefts (Figure 1.3c): Faulty growth of the folds results in the persistence of the primitive tracheo-esophageal space.

Recently, it has been shown that esophageal atresias and tracheo-esophageal fistulas can be induced by maternal application of Adriamycin into the peritoneal cavity of pregnant rats.[19,20] The dosage may vary between 1.5 and 2.0 mg/kg depending on the number of days it will be given. In most reports, the most promising dosage is 1.75 mg/kg given on days 6–9 of pregnancy. The Adriamycin model has been intensively studied over the last 20 years, resulting in more than 90 reports between 1997 and 2017.[88] It could be demonstrated that, in this model, not only foregut malformations but also atypical patterns of malformation can be observed, which are usually summarized under the term "VATER" or "VACTERL" association.[21,22] Therefore, this model is promising for the studies of not only foregut anomalies but also of anomalies of the hind- and midgut.

DEVELOPMENT OF THE DIAPHRAGM

In the past, several theories were proposed to explain the appearance of posterolateral diaphragmatic defects:

1. Defects caused by improper development of the pleuroperitoneal membrane[89,90]
2. Failure of muscularization of the lumbocostal trigone and pleuroperitoneal canal, resulting in a "weak" part of the diaphragm[89,91]
3. Pushing of intestine through the posterolateral part (foramen of Bochdalek) of the diaphragm[92]

4. Premature return of the intestines into the abdominal cavity with the canal still open[89,91]
5. Abnormal persistence of lung in the pleuroperitoneal canal, preventing proper closure of the canal[93]
6. Abnormal development of the early lung and posthepatic mesenchyme, causing nonclosure of pleuroperitoneal canals[18]

Of these theories, failure of the pleuroperitoneal membrane to meet the transverse septum is the most popular hypothesis to explain diaphragmatic herniation. However, using SEM techniques,[78] we could not demonstrate the importance of the pleuroperitoneal membrane for the closure of the so-called pleuroperitoneal canals (Figure 1.4).

As stated earlier, most authors assume that delayed or inhibited closure of the diaphragm will result in a diaphragmatic defect that is wide enough to allow herniation of gut into the fetal thoracic cavity. However, this assumption is not the result of appropriate embryological observations but rather the result of interpretations of anatomical/pathological findings. In a series of normal staged embryos, we measured the width of the pleuroperitoneal openings and the transverse diameter of gut loops.[82] On the basis of these measurements, we estimated that a single embryonic gut loop requires at least an opening of 450 μm in size to herniate into the fetal pleural cavity. However, in none of our embryos, the observed pleuroperitoneal openings were of appropriate dimensions. This means that delayed or inhibited closure of the pleuroperitoneal canal cannot result in a diaphragmatic defect of sufficient size. Herniation of gut through these openings is therefore impossible. Thus, the proposed theory about the pathogenetic mechanisms of CDH development lacks any embryological evidence. Furthermore, the proposed timing of this process is highly questionable.[79,80]

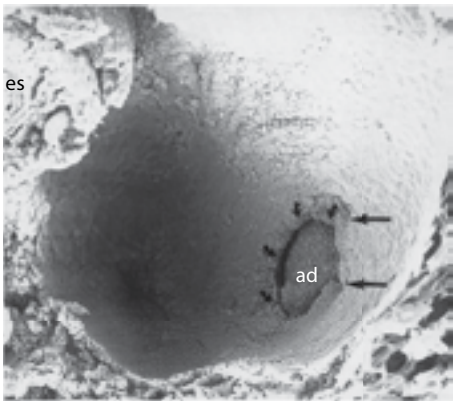

Figure 1.4 SEM photograph of right pleural sac in a rat embryo (approx. 16.5 days old). View from cranial. The so-called pleuroperitoneal canal (PPC) is nearly closed. Small arrows point at the margin of PPC. In the depth of the abdomen, the right adrenals (ad) are seen. Large arrows point at margins of the so-called pleuroperitoneal membrane. Its contribution to the closure of the canal is minimal (es, esophagus).

Recently, an animal model for diaphragmatic hernia has been developed[14–18] using nitrofen as the noxious substance. In these experiments, CDHs were produced in a reasonably high percentage of newborns.[15,16] Most diaphragmatic hernias were associated with lung hypoplasias. Using electron microscopy, our group[79–82] used this model to give a detailed description of the development of the diaphragmatic defect. Our results are as follows.

Timing of diaphragmatic defect appearance

Iritani[18] was the first to notice that nitrofen-induced diaphragmatic hernias in mice are not caused by an improper closure of the pleuroperitoneal openings but rather the result of a defective development of the so-called posthepatic mesenchymal plate (PHMP). In our study in rats, clear evidence of disturbed development of the diaphragmatic anlage was seen on day 13 (left side) and day 14 (right side, Figure 1.5).[79,82] In all embryos affected, the PHMP was too short. This age group is equivalent to 4–5 week old human embryos.[79]

Location of diaphragmatic defect

In our SEM study, the observed defects were localized in the PHMP (Figure 1.5). We identified two distinct types of defects: (1) large "dorsal" defects and (2) small "central" defects.[79] Large defects extended into the region of the pleuroperitoneal openings. In these cases, the closure of the pleuroperitoneal openings was usually impaired by the massive ingrowth of liver (Figures 1.6 and 1.7). If the defects were small, they were consistently isolated from the pleuroperitoneal openings closing normally at the 16th or 17th day of gestation. Thus, in our embryos with CDH, the region of the diaphragmatic defect

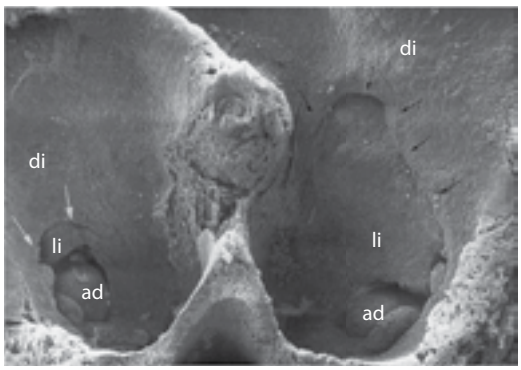

Figure 1.5 Cranial view of the pleural sacs in a rat embryo after exposition to nitrofen on day 11 of pregnancy. The embryo is approx. 15 days old. Note the big defect of the right diaphragmatic primordium. Small black arrows point at margins of the defect, which leaves parts of the liver (li) uncoated. On the left, the diaphragmatic anlage is normal. Note the low position of the cranial border of the pleuroperitoneal opening on this side (white arrows) (ad, adrenals; di, anlage of diaphragm).

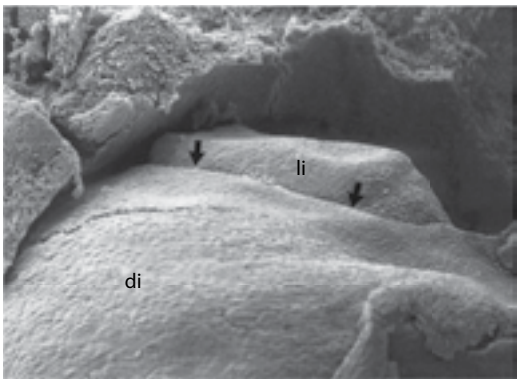

Figure 1.6 Liver (li) protrudes through diaphragmatic defect. Arrows point to the margin of the defect (di, diaphragmatic anlage). Rat embryo (approx. 16 days old), nitrofen exposition on day 11 of pregnancy.

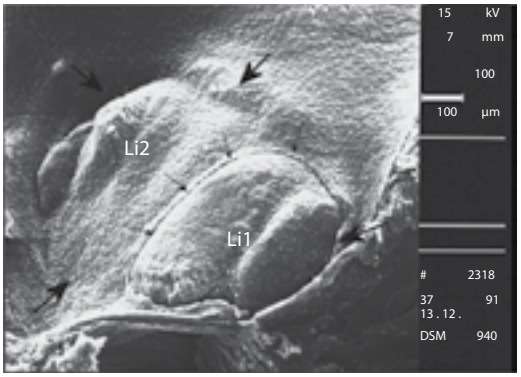

Figure 1.7 SEM photograph of a right pleural sac in a rat embryo after nitrofen exposure on day 11 of pregnancy. The embryo is approximately 15.5 days old. Note the big defect of the right dorsal diaphragm (large arrows). The closure of the pleuroperitoneal canal (PPC) is impaired by the ingrowths of liver (small arrows). Li1 = liver growing through PPC. Li1 + Li2 = liver growing through the defect of the diaphragm.

was a distinct entity and was separated from that part of the diaphragm where the pleuroperitoneal "canals" are localized. We conclude therefore that the pleuroperitoneal openings are not the precursors of the diaphragmatic defect.

Why lungs are hypoplastic

Soon after the onset of the defect in the 14-day-old embryo, liver grows through the diaphragmatic defect into the thoracic cavity (Figure 1.6). This indicates that, from this time on, the available thoracic space is reduced for the lung and further lung growth is hampered. In the following stages, up to two-thirds of the thoracic cavity can be occupied by liver (Figure 1.7). Herniated guts were found in our embryos and fetuses only in late stages of development (21 days and newborns). In all of these, the lungs were already hypoplastic when the bowel entered the thoracic cavity.[79]

Based on these observations, we conclude that the early ingrowth of the liver through the diaphragmatic defect is the crucial step in the pathogenesis of lung hypoplasia in CDH. This indicates that growth impairment is not the result of lung compression in the fetus but rather the result of growth competition in the embryo: the liver that grows faster than the lung reduces the available thoracic space. If the remaining space is too small, pulmonary hypoplasia will result.

DEVELOPMENT OF THE EMBRYONIC CLOACA (EC)

General remarks on the development of the EC

The terminology of malformations is sometimes confusing. As already mentioned, there is a strong belief that human embryos go through a phase in their development where they have a "cloaca." This belief is based on Haeckel's "biogenetic law."[5] According to this theory, a human embryo recapitulates in its individual development (ontogeny) the morphology observed in all life forms (phylogeny). This means that the development of advanced species passes through stages represented by adult organisms of more primitive species. This theory still has an impact on the nomenclature of embryonic organs.

Literature on "normal cloacal development"

In the literature, several theories have been put forward to explain the differentiation of the "cloaca" into the dorsal anorectum and the ventral sinus urogenitalis. To many authors, this differentiation is caused by a septum that develops cranially to caudally and thus divides the cloaca in a frontal plane. Disorders in this process of differentiation are thought to be the cause of "cloacal" anomalies such as "persistent cloaca" and anorectal malformations.

However, there is no agreement on the mechanisms of septation. While some authors[94,95] believe that the descent of a single fold separates the urogenital part from the rectal part by ingrowth of mesenchyme from cranial, others[96] think that lateral ridges appear in the lumen of the cloaca, which progressively fuse along the midline and thus form the septum. In a recent paper,[97] the process of septation had been questioned altogether.

Own observations

Using SEM techniques, our group studied cloacal development in rat and SD-mice embryos. The SD-mouse is a spontaneous mutation of the house mouse characterized by having a short tail (Figure 1.8). Homozygous or heterozygous offspring of these mice show skeletal, urogenital, and anorectal malformations.[25,28] Therefore, these animals are ideal for the study of the development of anorectal malformations.

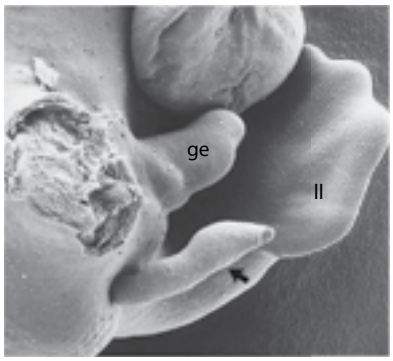

Figure 1.8 Characteristic short tail (arrow) of SD-mouse embryo (approx. 13 days old) (ll, left lower limb; ge, genital tuberculum, abnormal).

Normal "cloacal" embryology (rat)

As in the foregut of chick embryos, signs of median fusion of lateral cloacal parts could not be demonstrated during normal cloacal development in the rat. However, in contradiction to van der Putte,[97] we think that downgrowth of the urorectal fold takes place, although it is probably not responsible for the formation of "cloacal" malformations.

Abnormal "cloacal" embryology (SD-mouse)

"Cloacal" malformations are caused by improper development of the early anlage of the cloacal membrane as demonstrated in SD-mice embryos.[98,99] Our studies of abnormal "cloacal" development in SD-mice had the following results:

1. The basis of the pathogenesis of anorectal malformations is too short a cloacal membrane.
2. The anlage of the cloacal membrane is too short and results in a maldeveloped anlage of the "cloaca," which is missing in its dorsal part (Figure 1.9).
3. The caudal movement of the urorectal fold is impaired in the malformed "cloaca." Thus, the hindgut remains in abnormal contact with the urethral part. This opening is true ectopic and will develop into the recto-urogenital fistula (Figure 1.10).

It is interesting to note that the morphology of the anorectal malformations observed is very similar in all animal models used irrespective of the source of the malformed embryo (spontaneous mutation vs. chemically induced vs. transgenic models).

Critical remarks on the terminology of the "cloaca"

It must be kept in mind that the term "cloaca" is used to describe not only a transitional organ system in human

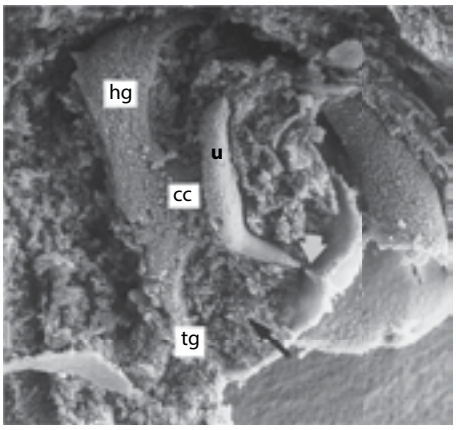

Figure 1.9 Malformed cloaca of SD-mouse embryo (approx. 11 days old). The surrounding mesenchyme is removed by microdissection. View on the basal layer of the cloacal entoderm. The cloaca has lost its contact to the ectoderm of the genitals (white arrow). The dorsal part of the cloaca is missing (black arrow). Tailgut (tg) and hindgut (hg) are hypoplastic. This malformed cloaca developed because the anlage of the cloacal membrane was too short in early embryogenesis (see text for details) (cc, rest of cloaca; u, urachus, rudimentary).

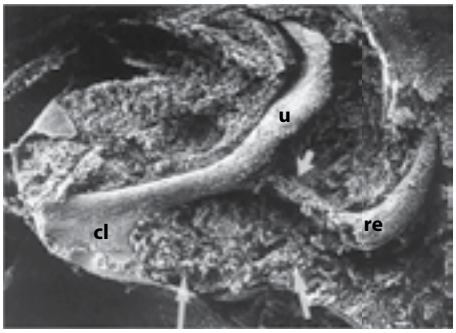

Figure 1.10 Malformed cloaca of SD-mouse embryo (approx. 13 days old). Urachus (u) and rectum (re) nearly normal (cl, ventral part of cloaca with short cloacal membrane). The dorsal part of the cloaca is missing (long white arrows). Short white arrow points to the region of the future fistula.

embryos but also a congenital anomaly in human female newborns and a normal organ in birds.[99]

This may lead to the false conclusion that the morphology of these three entities is similar. This is not the case. Despite the same name, embryonic "cloacas" are morphologically completely different from "cloacas" in female newborns with ARM. And these female "cloacas" are morphologically completely different from cloacas in birds.[100]

The main difference is the presence/absence and position of the anus:

1. In normal embryonic "cloacas," the future anal region is always present.
2. In human "cloacas," the anus is always missing.
3. In birds, the "cloaca" is part of the rectum.

Thus, the anus is always present in birds.

Furthermore, it is obvious that a true definition of the term embryonic "cloaca" is missing. In many papers and textbooks, it is replaced by observations made in female newborns born with the malformation called "cloaca." These are defined as defects "in which the rectum, one or two vaginas and the urinary tract converge into a common channel."[101]

It is believed that they represent malformations that occur in a very early stage of development.[101] Therefore, many authors believe that these malformations are "persistent cloacas."[101]

However, recent observations on the development of the vagina in mice[102] show that the development of the vagina and its downgrowth takes place after the complete separation of urethra and anorectum. As a result, a "cloaca" in the above-mentioned definition does not exist in normal embryos.

How can the female malformation called "cloaca" be explained? In our opinion, this malformation develops in two steps:

1. An anorectal malformation develops as described above.
2. The downgrowth of the vagina is hampered by the abnormal connection between urethra and anorectum (Figure 1.10).

HYPOSPADIAS

Many investigators[103–106] believe that the urethra develops by fusion of the paired urethral folds following the disintegration of the urogenital membrane. Impairment of this process is thought to result in the different forms of hypospadia.[106] However, in our study of normal cloacal development,[107] we were puzzled by the fact that disintegration of the urogenital part of the cloacal membrane could not be observed in rat embryos (Figure 1.11). This finding caused us to call in question the generally assumed concepts of hypospadia formation. Instead we found that

1. The urethra is always present as a hollow organ during embryogenesis of rats, and that it is always in contact with the tip of the genitals.
2. An initially double urethral anlage exists. The differentiation in female and male urethra starts in rats of 18.5 days old. On the other hand, we found no evidence for
   a. The disintegration of the urogenital cloacal membrane
   b. A fusion of lateral portions within the perineum

In our opinion, more than one embryological mechanism is at play in the formation of the hypospadias complex. The moderate degrees, such as the penile and glandular forms, represent a developmental arrest of the genitalia (Figure 1.12). They take their origin from a situation comparable

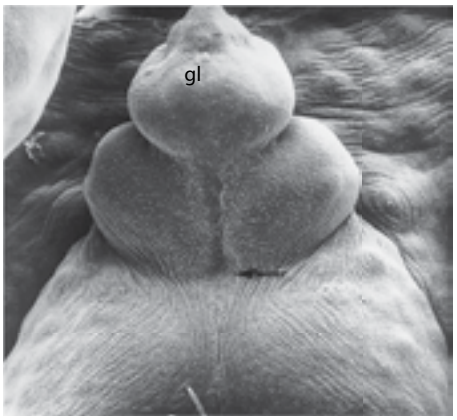

Figure 1.11 Genitals of a normal female rat embryo (approx. 18.5 days old) (gl, glans). Arrow points to future opening of the female urethra. No signs of disintegration of the cloacal membrane.

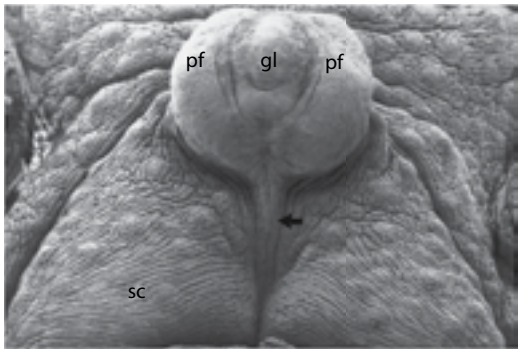

Figure 1.12 Genitals of a normal male rat embryo (approx. 20 days old) (gl, glans; pf, preputial fold; sc, scrotum). Arrow points to the raphe up to this stage; disintegration of the urogenital part of the cloacal membrane was not seen. Note similarity with clinical picture of hypospadia.

to the 20-day-old embryo. Consequently, the penis, not the urethra, is the primary organ of the malformation.

Perineal and scrotal hypospadias are different from the type discussed previously. Pronounced signs of feminization in these forms suggest that we are dealing with a female-type urethra. The origin of this malformation complex is an undifferentiated stage as may be seen in the 18.5-day-old rat embryo.[104]

CONCLUSION

Despite the long history of experimental embryology, we know very little about etiology and pathogenesis of congenital malformations. For decades, hypotheses were abundant while few data existed to support them. The tremendous progress of neighboring biological sciences is now providing powerful tools for researchers in the field, such as recombinant DNA and hybridoma technology. Future investigations will monitor closely how genes are switched on and

off during embryogenesis and determine the relation of spatial and temporal disturbances to ensuing malformations. Target structures of chemical or viral teratogens within the embryonic cells await identification. Finally, improved understanding of growth coordination in utero will extend to related areas such as wound healing and proliferation of cancer cells.

Transition to extrauterine life

CARLOS E. BLANCO AND EDUARDO VILLAMOR

INTRODUCTION

In order to succeed in this transition, the respiratory system must be developed enough to assure a sufficient alveolar exchange area, it must have a drive to offer a continuous breathing activity, and the circulatory system should start perfusing the lungs instead of the placenta.

This chapter will discuss the mechanisms preparing the fetus to be born, the transition at birth, and the successful adaptation to the air-breathing world. This chapter will review the respiratory system, the respiratory drive and chemoreceptor role, and the circulatory system including fetal circulation and its changes at birth.

FETAL CIRCULATION AND ITS TRANSITION AT BIRTH

EDUARDO VILLAMOR

The fetal circulation is characterized by high pulmonary vascular resistance (PVR), low systemic vascular resistance (SVR), presence of an additional low resistance vascular bed (i.e., the placental bed), and right-to-left shunting via the foramen ovale and ductus arteriosus (DA).[1] Distribution of blood flow to the lungs, systemic organs, and placenta is determined by local vascularl resistance. The placental vascular bed receives about 40%–50% of the combined ventricular output, whereas the lungs receive less than 10%. In response to fetal hypoxemia, distribution of cardiac output and venous return is altered in an effort to maintain perfusion and O_2 delivery to the vital organs such as the heart, brain, and adrenal glands.[2,3] Thus, during maternofetal hypoxia, the percentage of systemic venous blood not sent to the placenta for oxygenation is decreased, whereas the proportion of umbilical venous blood contributing to fetal cardiac output is increased.[2,3]

The human placenta was widely thought of as a passive organ in which blood flow depends only on the pressure difference between the umbilical arteries and vein connecting it to the fetus.[4,5] However, more recent evidences indicate that the regulation of vasomotor tone in the vessels of the fetoplacental circulation is important to maintain an adequate blood supply that makes possible maternofetal gas and solute exchange.[4–6] As fetoplacental blood vessels lack autonomic innervation, control of vascular tone is mainly influenced by circulating and/or locally released vasoactive agents as well as by physical factors, such as flow or oxygen tension.[7] Accordingly, constriction and relaxation of fetoplacental arteries and veins have been demonstrated in response to a number of agonists and physical stimuli. Moreover, various authors have suggested that the fetoplacental vasculature shows some form of flow matching similar to hypoxic pulmonary vasoconstriction. This mechanism, termed hypoxic fetoplacental vasoconstriction,[6,8,9] would divert blood flow to the placental areas with better maternal perfusion as hypoxic pulmonary vasoconstriction diverts pulmonary blood flow to the better ventilated areas of the lung.[9–11]

Separating the infant from the placenta by clamping the umbilical cord necessitates the rapid switch to pulmonary gas exchange within minutes of birth. This switch not only involves aeration of the airways and gas exchange regions of the lung but also includes a major reorganization of the fetal cardiovascular system.[12] As the lung assumes the respiratory function, the pulmonary circulation undergoes a striking transition characterized by an immediate 8- to 10-fold rise in pulmonary blood flow and a sustained decrease in PVR.[13–16] The postnatal fall in PVR and rise in SVR results in a reversal of the relationships present in the fetus. Moreover, pulmonary blood flow must have the capacity to replace umbilical venous return as the primary source of preload for the left ventricle when the cord is clamped.[12] Increasing blood return to the heart via the pulmonary veins raises the pressure of the left atrium above that of the right, causing a functional closure of the foramen ovale. While the DA is still patent, the flow of blood through it will change to a left-to-right shunt, but the DA normally achieves functional closure within 48 hours after birth. Because the foramen ovale and DA are only functionally closed and the pulmonary circulation is very sensitive

to vasoconstrictive stimuli, the neonatal circulatory pattern can readily revert to the fetal pattern. In the following paragraphs, the different circulatory events that take place during the transition between fetal and postnatal life will be analyzed in more detail.

Closure of the ductus venosus

The ductus venosus is a shunt between the umbilical vein and the inferior vena cava, which allows highly oxygenated and nutrient-rich umbilical venous blood to bypass the liver and reach the central circulation rapidly.[1] A large proportion of inferior vena caval return crosses the foramen ovale into the left atrium to the left ventricle, and is thus distributed to the coronary and cerebral circulations. The PO_2 of blood supplying the heart, brain, head, and neck is higher by 4–5 mmHg than that of blood in the descending aorta. Although the ductus venosus has received less attention than the DA, it is now well accepted that it plays a major role in the regulation of fetal circulation. Inlet of the vessel is under active control and a compensatory mechanism, supported by transient dilatation, is supposed to increase oxygenated blood flow through the ductus venosus during hypoxia or reduced umbilical flow.[17] Absence of the ductus venosus is associated with a high incidence of fetal anomalies and adverse outcomes, including associated malformations, chromosomal aberrations, in utero heart failure, and absence of the portal vein.[18] Functional closure of the ductus venosus, which is followed by anatomic closure, is virtually complete within a few weeks of birth. However, the ductus venosus of almost all neonates remains open for a certain period after birth with important variations in the volume of blood flow.[19] Closure of the ductus venosus is more delayed in preterm neonates, and patent ductus venosus appears to be related to alterations in ammonia detoxification, blood coagulation, and regulation of serum total bile acid concentration.[19]

Closure of the foramen ovale

Anatomically, the foramen ovale comprises overlapping portions of septum primum and septum secundum, acting as a one-way flap valve allowing continuous right-to-left flow during fetal life.[20] Immediately after birth, with the acute increase in pulmonary blood flow, left atrium pressure rises to exceed right atrium pressure, pushing septum primum rightward, against septum secundum, shutting the flap of the foramen ovale. Afterward, septum primum fuses to septum secundum, completing septation of the atria. However, in 20% to 25%, incomplete fusion leads to the persistence of the flap valve, leaving a patent foramen ovale.[20] In general, individuals with patent foramen ovale are never identified because they have no symptoms. However, there is increasing interest in the evaluation and treatment of patent foramen ovale, which has been associated with various pathologic conditions, such as cryptogenic stroke, decompression sickness, platypnea–orthodeoxia syndrome, and migraine.[21]

Fall in PVR

Although the regulation of the pulmonary circulation in the fetus and newborn is under many interacting and redundant signaling pathways, the ability to adapt to changes in the availability of O_2 is probably the most relevant.[22] The fetal lung is continuously exposed to a low O_2 tension, which induces a vigorous hypoxic pulmonary vasoconstriction.[14,23,24] This physiological level of hypoxia maintains the fetal type of circulation and also promotes normal vascular growth. However, an increase in the degree of hypoxia results in abnormal signaling and vascular remodeling.[14,23,24]

At birth, with the onset of breathing, PVR dramatically decreases and pulmonary blood flow increases such that the entire right ventricular output goes to the lung, as they assume the function of gas exchange. The hemodynamic changes in the pulmonary circulation after birth are regulated by various mechanical factors and vasoactive agents in a complicated but coordinated manner. These mechanisms not only are involved in the immediate postnatal fall in PVR but also help maintain the low PVR in the newborn and the adult. Besides the increase in O_2 tension, several other mechanisms contribute to the normal fall in PVR at birth, including the establishment of a gas–liquid interface in the lung, rhythmic distension of the lung, and shear stress.[13,14,25] These physical stimuli act, at least partially, through the production of vasoactive products. An increased release of vasodilators, in particular nitric oxide (NO) and prostaglandin $(PG)I_2$, and a decreased release of vasoconstrictors such as platelet activating factor (PAF) or endothelin (ET)-1, as well as changes in their signaling pathways, contribute significantly to the fall in PVR.[13,16,26,27] Normally, pulmonary arterial pressure falls to the half of the systemic pressure by 24 hours and then progressively decreases to adult levels within 2–6 weeks.[28] Therefore, the process of pulmonary circulatory transition is not limited to the first moments of extrauterine life, but it extends during the following weeks.[28]

Failure of the pulmonary circulation to undergo a normal transition results in persistent pulmonary hypertension of the newborn (PPHN), a clinical syndrome of various neonatal cardiopulmonary disorders that are characterized by sustained elevation of PVR after birth, leading to right-to-left shunting of blood across the DA or foramen ovale and severe hypoxemia.[14,16] PPHN is a pathophysiological phenomenon occurring in a heterogeneous group of diseases with a wide diversity of etiologies. These range from transient reversible pulmonary hypertension attributable to perinatal insults to irreversible fixed structural malformations of the lung. Diseases associated with the syndrome of PPHN can be classified in three categories[13,15]: (1) maladaptation, in which vessels are presumably of normal structure but have abnormal vasoreactivity; (2) excessive muscularization, in which smooth muscle cell thickness is

increased and muscle extends distally to vessels that usually are nonmuscular; and (3) underdevelopment, in which lung hypoplasia is associated with decreased number of pulmonary arteries. Either as a primary condition or secondary to other pulmonary or extrapulmonary diseases, PPHN is an important cause of cardiorespiratory failure and responsible for a relevant percentage of morbidity in the neonatal intensive care units.[13,15] The progress made in our understanding of the regulation of the perinatal pulmonary circulation has helped in the development of new treatments for PPHN, such as NO inhalation, PGI_2 inhalation, inhibition of cGMP degradation by type 5 phosphodiesterase with sildenafil, inhibition of cAMP degradation with milrinone, and inhibition of ET-1 with bosentan.[27]

Closure of the DA

The DA is distinguished from the surrounding vasculature by its embryologic derivation from the left sixth aortic arch, the contribution of migratory neural crest cells, and exquisite sensitivity to oxygen tension.[29] Low O_2 tension, high levels of circulating PGE_2, and locally produced PGE_2 and PGI_2 are the main factors maintaining patency of the DA in utero.[30–32]

Classically, the process of DA is divided into two sequential steps: functional and structural. However, it should be noted that these steps overlap and the causative agents may be shared.[33] Several events promote the constriction of the DA in the full-term newborn: (1) the increase in arterial PO_2, (2) the decrease in blood pressure within the ductus lumen (due to the postnatal decrease in PVR), and (3) the decrease in circulating PGE_2 (due to the loss of placental PG production and the increase in PGs removal by the lung), as well as the decrease in the number of PGE_2 receptors in the ductus wall.[30,31,34] Intertwined with functional closure, structural closure may encompass up to four distinct mechanisms of varying impact depending on the species[33]: (1) development of intimal cushions,[30,33] (2) mechanical solicitation from turbulent blood flow along the narrowing lumen,[33] (3) intramural hypoxia, which inhibits local production of PGE_2 and NO and induces production of growth factors,[30,33] and (4) interaction of platelets with the vessel wall, which adopts a prothrombotic phenotype.[35]

Perspectives

Despite the progress being made in understanding the regulation of the perinatal circulatory transition, much is left unknown. Evidence accumulated during the last two decades demonstrates that alterations in the production and actions of a number of vasoactive agents such as NO, ET-1, prostanoids, PAF, and reactive oxygen species are critically involved in promoting vascular remodeling and augmenting vasoreactivity that lead to PPHN. However, our knowledge about the regulation of the development of the pulmonary circulation at the genetic and molecular levels is scanty.[26] In addition, the cross talk among the multiple signaling pathways involved in the different cell types in the pulmonary vasculature needs to be better understood.[26]

A patient DA (PDA) in the first 3 days of life is a physiologic shunt in healthy term and preterm newborn infants. In contrast, failure of DA closure after birth is a common complication of premature delivery.[32] Even when it does constrict, the premature DA frequently fails to develop profound hypoxia and anatomic remodeling and is, therefore, susceptible to reopening.[34] PDA in preterm infants is associated with significant morbidities including intraventricular hemorrhage, necrotizing enterocolitis, and bronchopulmonary dysplasia. However, there is intense controversy regarding whether PDA is truly causative.[36] Furthermore, it is unknown if prophylactic and/or symptomatic PDA therapy will cause substantive improvements in outcome.[37] Therefore, there is still uncertainty and controversy about the significance, evaluation, and management of PDA in preterm infants, resulting in substantial heterogeneity in clinical practice. A large body of evidence now exists demonstrating that early, routine treatment to induce closure of the ductus in preterm infants, either medically or surgically, in the first 2 weeks after birth does not improve long term. The role of more selective use of medical methods for induction of ductal closure, either for defined high-risk infants in the first 2 postnatal weeks or for older infants with PDA, remains uncertain and requires further study.[38] The hope for future targeted therapies and for the prevention of PDA requires knowledge of the fundamental mechanisms controlling its development and pathogenesis.[36]

The immaturity of the fetal heart and circulatory system, along with pulmonary immaturity, creates many challenges in the care of very preterm infants. Given that premature infants begin extrauterine life before the fetal circulation has finished its maturation, very preterm infants manifest many of the functional and structural characteristics of the fetal cardiovascular system.[39] Therefore, the preterm neonate may not be able to adapt to the sudden increase in SVR because of the immaturity of the myocardium. This may negatively affect preload, afterload, contractility, heart rate, cardiac output, and systemic blood flow, leading to hypotension and possibly shock.[39,40] The immature myocardium has impaired contractility due to a decreased proportion of contractile elements, altered calcium release, altered titin function, decreased β-adrenoceptor number, and decreased sympathetic innervation.[39] When hypoxia associated with perinatal depression occurs at delivery, the myocardium is even more compromised, especially when coupled with acidosis.[39,40] An understanding of the development of the circulatory physiology can assist the practicing clinician with management of circulatory failure in the very preterm infant.[39] Delayed cord clamping, limiting iatrogenic blood loss, judicious use of volume expanders and inotropes for hypotension, and a more conservative approach for PDA are among the current recommendations and standards used in neonatology; but there is still a large amount of research that needs to be done, especially

stratifying studies specific to the extremely very low birth weight population.[40]

THE RESPIRATORY SYSTEM

CARLOS E. BLANCO

Fetal breathing movements (FBM)

Periodic non-air intrauterine breathing pattern must change at birth to a continuous air-breathing pattern. This change happens after clamping the umbilical cord, full perfusion of the lungs, changes in temperature, changes in behavioral state, increase in metabolism, increase in afferent input to the central nervous system, changes in levels of prostaglandins, and many other changes associated to the moment of birth.

Breathing-like activity in utero is present from very early in gestation and is the consequence of rhythmic activation of respiratory neurons in the brainstem[41,42]; however, these breathing movements play no part in fetal gas exchange. The efferent activity of these respiratory neurons activates the respiratory motoneurons and hence the muscles, mainly the diaphragm, which generate a negative intrathoracic pressure. In fetal lamb, spasm of the diaphragm at the 38th day of gestation (term 147 days) and rhythmic movements of the diaphragm at the 40th day of gestation have been described.[43] Chronic recordings from fetal lambs in utero performed at approximately 50 days of gestation showed two types of diaphragmatic activity: (1) unpatterned discharge and (2) patterned, bursting discharge.[44] In the human fetus, thoracic movements were observed from the 10–12th week of gestation.[45] At this time in gestation, there is still not a clear pattern and FBM appear to be more "freewheeling."

Later in gestation in the fetal lamb (75–110 days), movements of the diaphragm start to become periodic. At this age, they are often associated with nuchal muscle activity and rapid eye movements.[46,47] A more definitive pattern starts to appear at 108–120 days of gestation when breathing movements become organized into a more complex state, now associated with the presence of rapid eye movements and nuchal muscle activity.[46–49] At this time in gestation, the electroencephalographic activity, commonly known as electrocortical activity (ECoG), still does not show any signs of differentiation. However, by 120–125 days of gestation, the ECoG shows a clear differentiation into low-voltage, high-frequency activity (range 13–30 Hz; low-voltage electrocortigram activity [LVECoG]) and high-voltage, low-frequency activity (3–9 Hz; high-voltage electrocortical activity [HVECoG]).[46,50–52] At this gestational age, breathing movements are rapid and irregular, with a frequency of 0.1–4 Hz and amplitude of 3–5 mmHg, and they produce small movements of tracheal fluid (<1 mL).[53] There are now two clearly defined fetal behavioral states in the fetal lamb: there is no nuchal muscle activity during LVECoG, but rapid eye movements and FBM are present. Polysynaptic spinal reflexes are also relatively inhibited during the LVECoG state.[54] During HVECoG, there are no eye movements or FBM, but nuchal muscle activity is present and polysynaptic reflexes are stronger.[54] The link between ECoG state and FBM implies either that breathing activity is facilitated (or even stimulated) during LVECoG and/or that it is inhibited during HVECoG. During LVECoG, there is more neural activity in cortical and subcortical structures, including the brainstem reticular formation. This facilitatory state could increase the sensitivity for tonic stimuli, such as the level of arterial CO_2, and generate respiratory output. This hypothesis is supported by the observation that there are no breathing movements during fetal hypocapnia even during the LVECoG state.[55] Extending this idea, the absence of FBM during HVECoG could be due to a disfacilitation, as reported during quiet sleep in the adult when slow waves appear in the EEG.[56,57] Other evidence also leads us to believe that during HVECoG, there is an active inhibition of breathing activity because in fetal sheep, FBM and ECoG were dissociated after the brainstem was transected at the level of the colliculi.[58] Furthermore, FBM response to hypercapnia is limited to LVECoG activity in the intact fetus, but hypercapnia can produce continuous breathing in both LVECoG and HVECoG after small bilateral lesions made in the lateral pons.[59] The mechanisms, origin, and location for this inhibition are not clear, but it is known that it is of central origin, and that it can be overridden in utero and at the time of birth when breathing becomes continuous.

Control of fetal breathing movements

The work of Barcroft[60] gave rise to the concept that inhibitory mechanism, which descends from higher centers, is involved in producing apneic periods in the fetus. This inhibitory control develops during the second half of gestation. This work also showed that the inhibition of FBM by hypoxemia is not seen early in gestation, and the descending inhibitory processes develop later. While the inhibition of FBM in HVECoG and in hypoxia involves descending inhibitory processes, they do not necessarily utilize the same neural mechanisms. Barcroft employed similar brainstem transection techniques to those of Lumsden[61] to show that neural structures above the level of the pons do not exert significant control over FBM. These studies were extended by Dawes and coworkers[62] who employed the technique of transection in the chronically instrumented late gestation fetal sheep. They showed that transection at the level of upper midbrain/caudal hypothalamus resulted in FBM, which were episodic but not related to the ECoG. These FBM were still inhibited by hypoxia. This makes it clear that the processes that mediate the inhibition of FBM in HVECoG are different from those that produce the inhibition in hypoxia. Transection through the rostral pons/caudal midbrain produced FBM that occurred almost continuously and were not inhibited by hypoxia. This focused attention on the upper pons in the inhibition of fetal breathing movements in hypoxia. Gluckman and

Johnston[63] pursued this by making lesions in the rostral lateral pons, and compiled a diagram showing areas not needed for the inhibition to be manifest, and the location of an area in the lateral pons that, if lesioned bilaterally, prevented the inhibition.

One of the key questions that emerged from these brainstem studies was whether the descending inhibitory mechanism is capable of inhibiting the input from peripheral chemoreceptors. Once it had been established that the peripheral chemoreceptors are active in utero and respond to natural stimuli such as hypoxia or hypercapnia (see section "Peripheral chemoreceptor function in utero"), it was no longer necessary to view the effect of modest hypoxia in inhibiting FBM as a direct depression of the medulla. The results of transection and lesion studies suggested that stimulation of FBM occurred during hypoxia after the damage to the brainstem, as if a stimulatory effect of the peripheral chemoreceptors had been unmasked. Direct confirmation of this idea came from the study of Johnston and Gluckman[64], who conducted a two-stage procedure: first, lesions were placed as before in the brainstem to prevent the inhibition of FBM in hypoxia or to give an overt stimulation; this was then prevented by chemodenervation at a second operation.

The nature (and indeed the location) of the inhibitory processes is not known. Because the inhibition occurs even in chemodenervated fetuses,[65] it is clear that the neurons involved do not receive an excitatory input from the chemoreceptors. They may therefore be chemoreceptors themselves or receive input from other cells thought to be sensitive to hypoxia, e.g., in the rostral ventrolateral medulla.[66] The neural activity as a whole behaves as a chemoreceptor, because the chemoreceptor stimulant drug almitrine mimics the effects of hypoxia in inhibiting FBM, irrespective of the integrity of the peripheral chemoreceptors.[67] As expected from the discussion above, the stimulatory effect of the drug on the peripheral chemoreceptors only becomes manifest when lesions were placed in the lateral pons,[68] unmasking its peripheral actions.

Peripheral chemoreceptor function in utero

The concept that peripheral chemoreceptors could produce effects on breathing can be traced to experiments conducted over 50 years ago in which breathing was shown to be stimulated in exteriorized midgestation animal fetuses by hypoxia or cyanide.[69] In late gestation, the descending inhibitory effects on breathing arising from the fetal brainstem in hypoxia and with HVECoG (see above) dominate. It was perhaps the increasing interest in these processes that caused the scientific community to lose sight of the implications of the earlier observations. The idea became prevalent that the carotid chemoreceptors were quiescent in utero and were activated at birth, perhaps by the increase in sympathetic nervous activity. In addition, when it became clear that normal fetal arterial PO_2 in late gestation, both in the sheep and the human fetus, was about 3 Kpa (25 mmHg), it was thought that if the chemoreceptors were functional, they would be so intensely stimulated that powerful reflex effects would be induced continuously. This was clearly not the case, although it had been shown that brainstem transection removed inhibitory effects on breathing[60,62] and permitted stimulation of breathing activity during hypoxia. It was therefore essential to readdress the question of arterial chemoreceptor function in utero. It was found that both carotid[70] and aortic[71] chemoreceptors were spontaneously active at the normal arterial PO_2 in fetal sheep, and that they responded with an increase in discharge if PO_2 fell or PCO_2 rose. There were several very important implications of these findings. First, it was clear that the peripheral chemoreceptors would be able to stimulate fetal breathing under some circumstances, but that it was the balance between this stimulatory input and the normally dominant, inhibitory input from higher centers that determined the characteristics of fetal breathing (see above). Second, it redirected attention to the role the carotid chemoreceptors play in initiating cardiovascular reflex responses to hypoxia.[72,73] Last, the observation that the fetal peripheral chemoreceptors discharge spontaneously (at about 5 Hz) at the normal fetal arterial PO_2 made it clear that the rise in PO_2 at birth would silence them. Their sensitivity to PO_2 would then have to reset to the adult range postnatal, and this has generated research into the mechanisms of this resetting.[74,75]

Pharmacological control

Prostaglandins exert a powerful influence on FBM and postnatal breathing. Prostaglandin E2 (PGE2) decreases the incidence of FBM,[76] whereas meclofenamate and indomethacin, inhibitors of PG synthesis, increase FBM.[77–79] The effect of prostaglandins appears to be central, as it is independent of the peripheral chemoreceptors[80] and because central administration of meclofenamate stimulates FBM.[81,82] The same effects can be produced postnatally, with PGE2 decreasing, and meclofenamate and indomethacin increasing, ventilation in lambs.[83,84] However, the change in the concentration of PGE2 that occurs around birth cannot be solely responsible for either the decrease in FBM seen immediately before birth[79,85] or the onset of continuous breathing postnatally.[86] The well-established effects of ethyl alcohol to reduce the incidence of FBM[87] are not mediated by prostaglandin[88] but by adenosine.[89]

Bennet et al.[90] showed that large doses of thyroid releasing hormone (TRH) can induce stimulation of FBM. This effect may be at the level of the respiratory neurons where TRH can be localized, but its physiological significance is not known. This may also be true of the effects of the cholinergic agonist, pilocarpine, and serotonin (5-HT) precursor L-5-hydroxytryptophan (L-5-HTP).[91,92] Both of these agents stimulate FBM, but pilocarpine induces LVECoG and L-5-HTP induces HVECoG. This stresses again the coincidental rather than causal relationship between FBM and LVECoG. 5-HT has been implicated in neural mechanisms

controlling adult sheep, but that the site of action in the fetus is not known. A range of opiates has effects on FBM,[93] but the physiological localization of their effects has not been established.

The high rate of progesterone synthesis by the placenta in late gestation exposes the fetus to high concentrations of progesterone and its metabolites. Progesterone can influence fetal behavior, and normal progesterone production tonically suppresses arousal, or wakefulness in the fetus.[94,95]

Last, one of the striking aspects of FBM is that FBM cease 24–48 hours before parturition. The mechanism involved is not known. Kitterman et al.[77] excluded a rise in plasma PGE_2, and Parkes et al.[96] showed that it did not occur if the fall in plasma progesterone was prevented.

Lung growth associated to FBM

Fetal breathing movements are necessary for fetal lung growth and maturation. By opposing lung recoil, FBM help to maintain the lung expansion that is now known to be essential for normal growth and structural maturation of the fetal lungs. FBM induce complex and variable changes in thoracic dimensions; these induce small alterations in the shape of the lungs that may act as a stimulus to lung growth. The prolonged absence or impairment of FBM is likely to result in a reduced mean level of lung expansion, which can lead to hypoplasia of the lungs.[97] Moreover, static distension decreases steady-state SP-A and SP-B mRNA levels in whole lung, whereas cyclic stretching increases SP-B and SP-A expression two- to fourfold and enhances 3H-choline incorporation into saturated phosphatidylcholine.[98]

Changes at birth

At birth, breathing activity must become continuous in order to fulfil its gas exchange function. After occlusion of the umbilical cord, the neonatal ECoG still cycles between low- and high-voltage states, which seem to have identical spectral characteristics to the fetal states. LVECoG activity is associated with the absence of nuchal muscle activity, rapid eye movements, and inhibition of polysynaptic reflexes, and HVECoG is associated with presence of nuchal muscle activity, lack of rapid eye movements, and enhanced polysynaptic reflexes.[99] However, despite the fact that after birth the HVECoG state seems to be similar to the equivalent fetal state, breathing activity is present.

Studies of the mechanisms involved in the establishment of continuous breathing at birth have followed two lines: (1) attempts to induce continuous breathing in utero or (2) observation of establishment of continuous breathing during situations aimed at mimicking birth.

It is well established that the inhibition of FBM during HVECoG can be overridden as demonstrated by the presence of continuous breathing during metabolic acidosis,[100,101] administration of prostaglandin synthetase inhibitors,[77,78,82] 5-hydroxytryptophan,[102,103] catecholamines,[103] pilocarpine,[91] thyrotrophin releasing hormone,[104] corticotrophin releasing factor,[90] central or peripheral fetal cooling,[105,106] and by lesions within the CNS (see above). These experiments show that FBM can become continuous through the operation of various mechanisms including disinhibition during HVECoG, changes in the balance between stimulatory and inhibitory neuromodulators, increased arousability, and changes in chemoreceptor sensitivity.[107] Some, but not all, of these mechanisms are likely to play an important role at birth.

Experiments designed to observe changes in breathing activity after cord occlusion have led to two main hypotheses: (1) The exclusion of fetal–placental circulation leads to the disappearance of hormones or neuromodulators, which exert continuous tonic inhibition (through the CNS) during fetal life, and that this allows continuous breathing postnatally.[108–111] There are reports indicating that prostaglandins originating from placental tissue can inhibit fetal breathing activity.[112] Although this is a possible explanation, it is not yet demonstrated that such a substance is responsible for the modulation by ECoG of FBM. It was shown that breathing movements of goat fetuses maintained in an extrauterine incubation system for more than 24 hours were episodic, suggesting that intermittent breathing movements are intrinsic to the fetus, independent of placenta-derived factors.[113] (2) Breathing activity is dependent on the level of $PaCO_2$ in utero and at birth.[55] It is known that during hypocapnia, fetal and neonatal breathing is reduced.[55,106,108] Hypercapnia stimulates breathing activity, but in utero, this is inhibited during quiet sleep. However, this inhibition can be overridden after lesions in the lateral pons[59] or when hypercapnia is combined with cooling.[106] This might be explained by changes in the CO_2 sensitivity of central and/or peripheral chemoreceptors or due to changes in the balance between central inhibitory and excitatory mechanisms caused by an increase in afferent input at birth. In this hypothesis, both changes in afferent input from chemoreceptors and thermoreceptors to the CNS, and/or changes in CNS sensitivity to these inputs, are important in the transition from fetal to neonatal breathing. Changes in the plasma level of a placental neuromodulator at birth may then serve to maintain postnatal breathing after its initiation. More insights into these mechanisms may offer an explanation for the occurrence of apneic periods after birth.

Postnatal breathing

Studies to identify brainstem mechanisms that regulate breathing have been conducted in the neonate, in which hypoxia also inhibits breathing but after a transient chemoreceptor-mediated stimulation. Therefore, the reasoning is that similar inhibitory processes to those that operate in the fetus produce the postnatal inhibition of ventilation by hypoxia. Transection of the brainstem through the rostral pons does indeed remove the secondary fall in ventilation[114] as does placement of lesions in the lateral pons[115]. However, these studies did not identify any clear group of neurons involved in mediating the effect. Investigators focused their attention on the red nucleus,

located above the pons in the mesencephalon. The transection studies implicate structures in either the rostral pons or caudal mesencephalon, so it is likely that the red nucleus would have been affected. In neonatal rabbits, electrical stimulation of the red nucleus produces a profound inhibition of respiratory output, and bilateral lesions in the red nucleus prevent the inhibition of respiratory output in hypoxia while not affecting the cardiovascular responses. Evidence that neurons in the red nucleus are involved in this effect comes from the observation that chemical stimulation with glutamate also produces an inhibition of respiratory output.[116] Interestingly, the efferent pathway for these cells, rubrospinal tract, runs in precisely the ventrolateral region of the pons lesioned by Gluckman and Johnston[63] in their fetal studies.

The observations on the red nucleus are interesting because in postnatal life, it has been implicated in producing the hypotonia of postural muscles, which occurs in REM sleep. Such hypotonia also occurs in the fetus,[70] but at that time, it is associated with presence, and not absence, of FBM. Once again, behaviorally related and hypoxia-induced inhibition of FBM appears to be distinct. In addition, the brainstem reticular formation and related nuclei associated with sleep and arousal have not been greatly studied in the postnatal period. In one study, Moore et al.[117] reported that cooling the locus coeruleus by a few degrees, sufficient to reduce neuronal activity but not conducted action potentials, prevented the secondary fall in ventilation in hypoxia in neonatal lambs. The locus coeruleus has been implicated in producing arousal at birth.[118] There are also reports that structures as high in the brain as the thalamus are implicated in the descending inhibition of breathing during hypoxia.[119]

While the effects of acute hypoxia on FBM have been widely studied, the effects of prolonged hypoxemia are quite different. Over a period of 6–12 hours, FBM return to their control incidence as does cycling of the ECoG.[120] Studies reveal that the peripheral chemoreceptors are necessary for the return of fetal breathing movements during sustained hypoxia produced by reduced uterine blood flow, but the mechanisms involved are not known.[121]

CONCLUSIONS AND FURTHER DIRECTIONS

Spontaneous breathing movements are present during fetal life, and they are important for normal development of the fetal lungs. Early in gestation, they seem to represent free-running activity of the respiratory centers, not controlled by peripheral mechanisms but probably dependent on a tonic CO_2 drive. Maturation of sleep states brings into play powerful brainstem inhibitory mechanisms that control this activity.

Fetal breathing activity is present during physiological and normal fetal conditions, and it can be monitored non-invasively by ultrasound; therefore, its monitoring could be used to interrogate fetal well-being. A recent Cochrane systematic review did not support its usefulness when included in a biophysical profile to detect high-risk fetuses.[122] However, the monitoring of fetal breathing activity could be used to predict premature labor.[123] Moreover, there is limited information showing the usefulness of monitoring fetal breathing and body activity during maternal physical activity. More research will be welcomed to assess and determine the intensity of maternal physical activity on the developing fetus.[124]

Birth clearly involves some irreversible processes, the transition to continuous breathing being one. However, breathing remains linked to behavioral and sleep states in the neonate as in the fetus, and clearly there is continuity of some control processes from late gestation to early postnatal life. Some of these processes mature relatively slowly after birth such as resetting of chemoreceptor hypoxia sensitivity and the diminishing influence of descending inhibitory effects on breathing in hypoxia. Understanding these effects will be of vital importance to prevention of SIDS and the care of newborn, especially preterm babies.

Clinical anatomy of the newborn

MARK D. STRINGER AND S. ALI MIRJALILI

INTRODUCTION

A newborn infant more than triples in height and increases in weight some 20-fold before reaching maturity. During the process, structures change in size and position. Some, which are critically important during fetal development, disappear. Most persist but grow at different rates at different ages. It is therefore not surprising that newborn anatomy differs from adults; some of these differences are particularly important for the pediatric surgeon (Table 3.1 and Figure 3.1). This chapter summarizes the applied anatomy of the newborn, emphasizing aspects that are clinically relevant and different to adults.

GROWTH AND PROPORTIONS

Growth can be defined as "the progressive development of a living being or any of its parts from its earliest stage to maturity, including the attendant increase in size."[1] It involves changes in size and mass, and includes processes such as cell division, specialization, and apoptosis. Growth can be proportional but is often differential. For example, the head of a full-term newborn infant accounts for about 25% of its body length and 20% of its body surface area. In adults, these figures are about 13% and 9%, respectively (Figure 3.2). Similarly, the pelvis and lower limbs are proportionately small in the neonate.[2] Body surface area to weight ratio decreases with age: the surface area of a neonate is about 0.25 m^2 compared to 1.73 m^2 in an adult. Neonates are consequently more vulnerable to heat loss.

The mean length of the full-term newborn measured from crown to heel is around 48–50 cm and weight 2.7 to 3.8 kg. About 75%–80% of this weight is water and 15%–28% is fat.[3] By 1 year of age, total body water has decreased to adult values of around 60% of body weight.

CARDIOVASCULAR SYSTEM

Circulatory changes after birth

In the fetus, oxygen-rich blood is transported from the placenta via the umbilical vein to the left branch of the portal vein lying within the umbilical recess of the liver (Figure 3.3). The ductus venosus arises from the posterior aspect of the left branch of the portal vein directly opposite the opening of the umbilical vein and passes superiorly and laterally between the left lobe and caudate lobe of the liver to terminate in the left hepatic vein near its entry into the inferior vena cava (IVC). A valve along the anterior margin of the opening of the IVC into the right atrium directs the oxygenated blood through the foramen ovale to the left atrium. Deoxygenated systemic blood returning from the fetal superior vena cava and coronary sinus is directed preferentially to the right ventricle. However, during late gestation, only about 20% of the fetal cardiac output reaches the lungs[4,5] because the ductus arteriosus shunts blood from the pulmonary trunk to the aortic arch, just distal to the origin of the left subclavian artery. At term, the ductus arteriosus is about 8–12 mm long and 4–5 mm wide at its origin from the pulmonary trunk; the thoracic aorta by comparison measures about 5–6 mm in diameter.[3] The walls of the ductus arteriosus are rich in smooth muscle fibers. In the fetus, ductal patency is maintained by locally produced prostaglandins, which inhibit muscle contraction in response to oxygen.

At birth, the lungs inflate and, as a result of mechanical effects and oxygen-induced pulmonary vasodilatation, pulmonary vascular resistance falls. The ductus arteriosus starts to close and pulmonary blood flow increases. Increased venous return to the left atrium causes a rise in left atrial pressure. Right atrial pressure falls as a result of reduced venous return secondary to occlusion of the

Table 3.1 Key anatomical differences between neonates and adults

Cardiovascular System	Recent transition from fetal circulation
	Relatively large heart
	Potential for congenital heart defects
	Prominent thymic shadow on chest x-ray
Respiratory System	Obligate nose breathing
	Short neck with high larynx
	Ability to breathe while suckling
	Subglottis is narrowest part of the airway
	Highly compliant chest wall
	Greater reliance on diaphragm for breathing
Abdomen	Relatively wide abdomen
	Short inguinal canal
	Propensity to inguinal hernias and undescended testes
	Small amount of intra-abdominal fat
	Proportionately large liver
	Poor radiological distinction between small and large bowel
	Small pelvic cavity
	Intra-abdominal bladder and body of uterus
	Proportionately large suprarenal glands
Musculoskeletal System	Proportionately large head, small pelvis, and lower limbs
	Open fontanels
	Relatively underdeveloped face and mandible
	Horizontal auditory tube
	No spinal curvatures (other than shallow sacral curve)
	Absence of most secondary ossification centers
	Shallow acetabulum
	Relatively small gluteal muscles
Nervous System	Relatively large brain with full complement of neurones
	but incomplete myelination of axons
	Proportionately large cerebral ventricles
	Spinal cord terminates at lower level
Skin	Variable subcutaneous fat (some brown fat)
	Thin skin, immature sweating
	Greater body surface area to weight ratio
	Head accounts for 20% of body surface area

umbilical vein. These changes in atrial pressure force the free lower edge of the primary atrial septum to flatten against and subsequently adhere to the margins of the fossa ovale, resulting in functional closure of the foramen ovale. A permanent seal usually develops during the first year of life.

Cardiovascular adaptation to neonatal life therefore requires the functional closure of three fetal conduits:

- *Foramen ovale*. Incomplete fusion of the primary atrial septum with the limbus of the fossa ovale occurs in up to 25% of individuals,[6] resulting in a small potential atrial communication, a patent foramen ovale (PFO). Typically this has no consequences because of the flap-like arrangement of the opening and differential atrial pressures. However, a PFO may rarely be associated with paradoxical embolism (passage of an embolus from the venous system through an abnormal communication between the chambers of the heart causing a systemic arterial embolus, e.g., an embolic stroke) and an increased risk of decompression sickness in divers.[7] After closure of the foramen ovale, the valve of the IVC that was prominent in the fetus becomes flimsy or disappears.
- *Ductus arteriosus*. In full-term neonates with no congenital heart disease, the ductus arteriosus starts to close immediately after birth. Smooth muscle contraction within the ductus produces an initial functional closure and is probably mediated by several mechanisms: an increased arterial oxygen concentration, suppression of endogenous prostaglandin E2 synthesis, plasma catecholamines, and neural signaling. In addition, ductal blood flow is reversed as a result of increased systemic vascular resistance (due to absence of the placental circulation) and decreased pulmonary vascular resistance. Functional closure is complete within 3 days in more than 90% of term infants.[8]

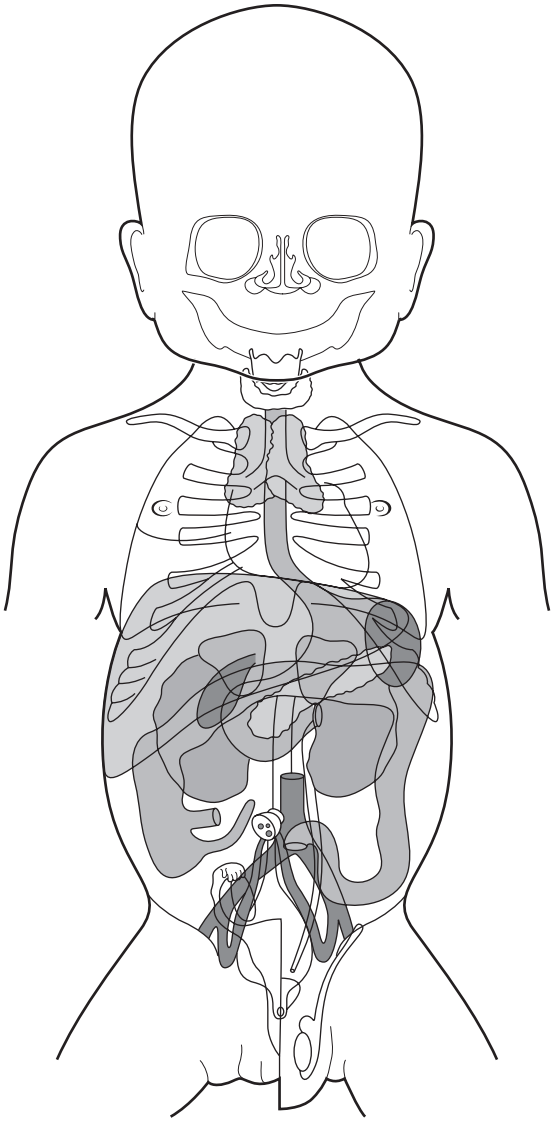

Figure 3.1 Diagram illustrating the relative proportions of viscera in the newborn. (Adapted from Crelin ES. *Functional Anatomy of the Newborn*. New Haven: Yale University Press, 1973, p. 75.)

Structural closure occurs more gradually, leaving the fibrous ligamentum arteriosum connecting the origin of the left pulmonary artery to the underside of the aortic arch. Persistent ductal shunting frequently occurs in preterm infants with respiratory distress.[4]

- *Ductus venosus*. Spontaneous closure of the ductus venosus begins immediately after birth[9] and is usually complete by about 17 days of age.[10,11] Closure may be temporarily delayed in the presence of congenital heart disease, presumably as a result of elevated venous pressure. In the adult, the remnant ligamentum venosum runs within the fissure separating the anatomic left lobe of the liver and the caudate lobe. Persistent patency of the ductus venosus is rare, is more common in boys, and may cause long-term problems such as hepatic encephalopathy.[12]

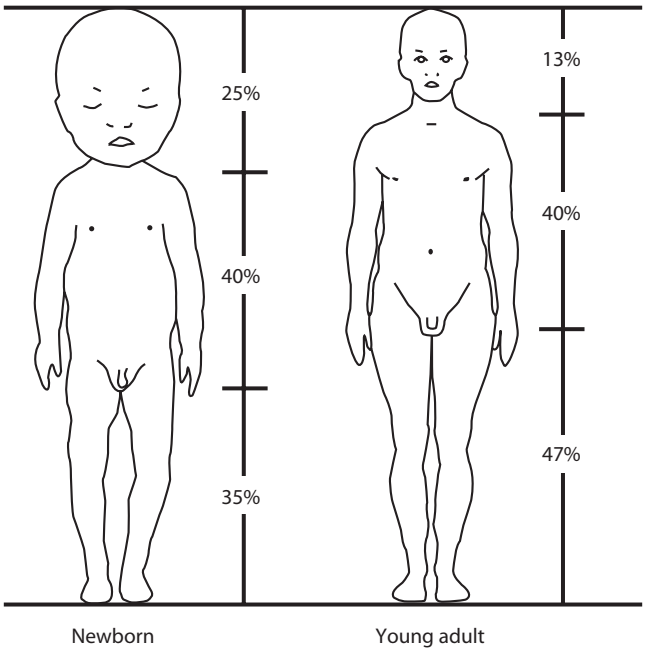

Figure 3.2 Relative proportions of the head, trunk, and lower limbs in a neonate and adult. (Adapted from Diméglio A. Growth in pediatric orthopaedics. In Morrissy RT, Weinstein SL. *Lovell and Winter's Pediatric Orthopaedics*. 6th edn. Lippincott Williams and Wilkins, 2006, Vol 1, p. 40.)

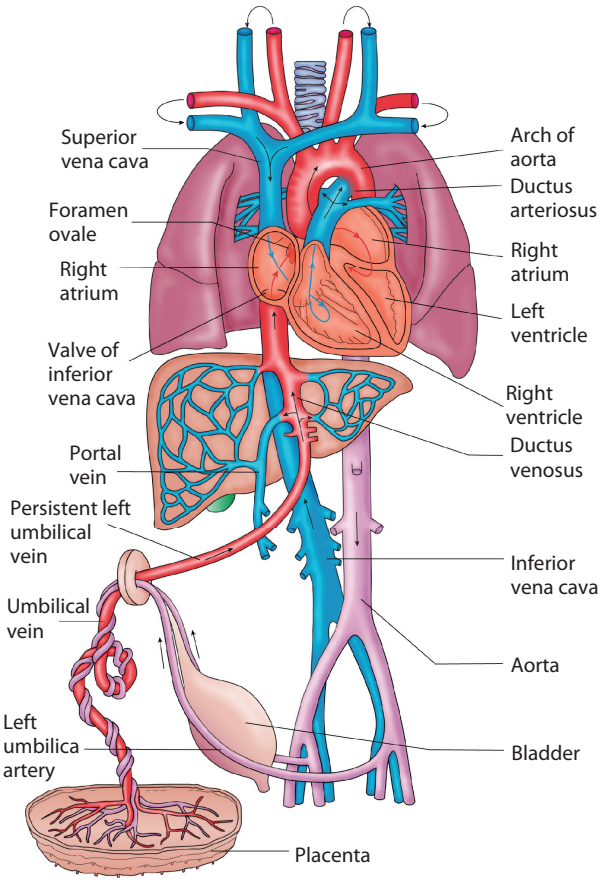

Figure 3.3 Fetal circulation.

The heart

In the full-term neonate, cardiac output measured by Doppler studies is about 250 mL/kg/min, mean systolic blood pressure in the first week is 70–80 mmHg (lower in preterm infants), and heart rate settles within hours of delivery to 120–140 beats/min. As the pulmonary circulation is established, the work of the right side of the heart decreases and the left increases, reflected by changes in ventricular muscle thickness; at birth, the mean wall thickness of both ventricles is about 5 mm, whereas in adults, the left ventricle is about three times as thick as the right.[3] The neonatal heart is relatively large in relation to the thorax and lungs, and consequently, it occupies a larger proportion of the lung fields on a chest radiograph compared to an adult (Figure 3.4[13]).

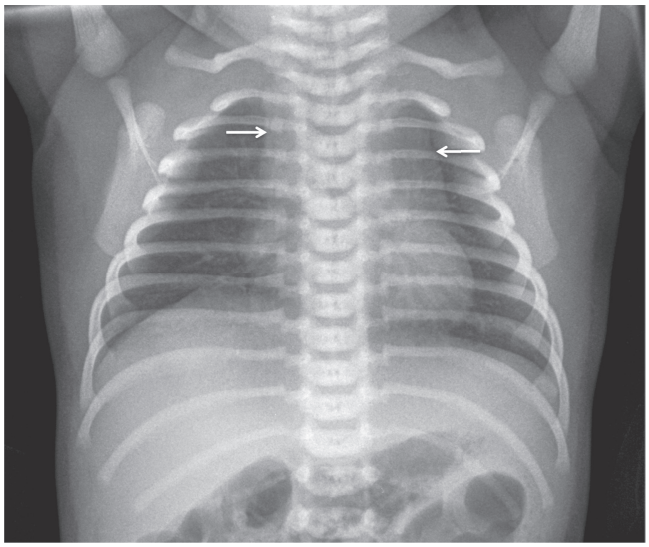
Congenital cardiac malformations account for up to a quarter of all developmental anomalies (8 per 1000 live births[4]) and include dextrocardia (isolated or part of situs inversus), isomerism, and structural defects (septal defects, abnormal atrioventricular or ventriculoarterial connections, and valvular anomalies). Ventriculoseptal defects are the most frequent, more often affecting the membranous than the muscular part of the interventricular septum. A true atrial septal defect occurs when there is a failure of normal development of the septum primum and/or atrioventricular endocardial cushions. Coarctation of the aorta is often included within the spectrum of congenital heart disease. Typically, there is narrowing or occlusion of the juxtaductal segment of aorta just distal to the origin of the left subclavian artery, although preductal (involving the aortic arch and its branches) and even postductal coarctation can occur.

Neonatal central venous catheters are generally positioned such that the catheter tip lies at the SVC/RA junction on a chest radiograph in order to reduce the small but serious risk of atrial perforation and cardiac tamponade.[14]

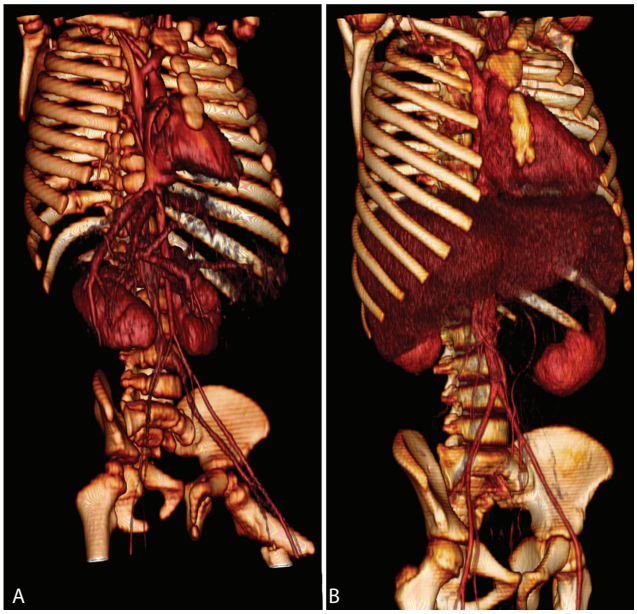
Umbilical vessels

The normal umbilical cord contains two thick-walled umbilical arteries and, near the 12 o'clock position, one larger but thin-walled umbilical vein. The presence of a single umbilical artery is associated with an increased risk of other congenital anomalies, particularly renal, vertebral, cardiovascular, and anorectal malformations,[15] and an increased risk of prematurity, growth restriction, and perinatal mortality.[16,17] However, routine karyotyping and renal sonography in an infant with an isolated single umbilical artery is not generally recommended.[16,18]

At birth, the umbilical vessels constrict rapidly in response to a fall in umbilical cord temperature and hemodynamic changes. Occlusion of the umbilical artery is facilitated by the "folds of Hoboken," constriction rings along the length of the umbilical artery produced by oblique or transverse bundles of myofibroblasts.[19] Numerous mediators of umbilical vessel vasoconstriction have been proposed,



(a)



(b)

Figure 3.4 **(a)** Supine anteroposterior neonatal chest radiograph. Note the prominent superior mediastinal thymic shadow (white arrows). Compared to an adult, the hemidiaphragms are relatively flat, the ribs are more horizontal, and the heart size is relatively large (although the transverse cardiothoracic ratio should still be less than 60%). **(b)** 3-D reconstructed CT scan of a neonate (A) and 10-year-old child (B) demonstrating differences in skeletal anatomy including chest shape and rib alignment.

including bradykinin and endothelin-1, some of which are produced locally within the umbilical cord. After birth, the obliterated umbilical arteries become the paired medial umbilical ligaments usually visible under the peritoneum of the anterior abdominal wall below the umbilicus; the proximal parts of each umbilical artery remain patent as the superior vesical artery. The intra-abdominal segment of the umbilical vein becomes the ligamentum teres. The urachus has

normally involuted before birth leaving the fibrous median umbilical ligament.

The umbilical artery and vein can be catheterized within 24–48 h of birth to provide vascular access for resuscitation, intravascular monitoring, fluid administration, blood transfusion, and parenteral nutrition.[20] The ideal position for the tip of an umbilical venous catheter is in the IVC, just below the right atrium. The tip of an umbilical artery catheter is usually positioned above the diaphragm but below the ductus arteriosus ("high" position equivalent to T6-9 vertebral level). Sometimes, the catheter tip is sited below the origin of the renal and inferior mesenteric arteries but above the aortic bifurcation ("low" position at L3-4 vertebral level).

Arteries

The femoral artery is palpable midway between the anterior superior iliac spine and pubic tubercle in the neonate[21]; it is therefore more lateral than in an adult where the surface marking is midway between the anterior superior iliac spine and symphysis pubis.[3] The renal arteries have been stated to lie at a higher vertebral level in the neonate than the adult, but recent studies have shown that they are around the level of L1 in both age groups.[22,23] The aortic bifurcation is at the upper rather than the lower border of L4.

Central veins

As in adults, the right and left brachiocephalic veins are formed by the union of the internal jugular and subclavian veins behind the ipsilateral sternoclavicular joint, and the junction between the superior vena cava and right atrium is most commonly behind the right fourth costal cartilage.[24,25] The left brachiocephalic vein lies at a relatively higher level than in adults and is potentially at risk of injury during tracheostomy when the neck is extended.

RESPIRATORY SYSTEM

Upper airway

Relative to an adult, the newborn infant has a large head, short neck, small face and mandible, and large tongue.[26,27] The entire surface of the tongue is within the oral cavity, unlike the adult where the posterior third is in the oropharynx. Neonates are obligate nose breathers and do not begin to breathe orally until about 4 months of age. All these features predispose to upper airway obstruction.

The neonatal nasopharynx curves smoothly backward and downward to join the oropharynx, rather than almost at a right angle as in adults (Figure 3.5).[27] The hyoid bone and larynx are high in the neck. Consequently, the upper margin of the neonate's epiglottis extends to the level of the soft palate, and the nasopharynx is in direct continuity with the larynx. This allows the infant to breathe while suckling. Ingested liquids pass lateral to the epiglottis via the piriform fossae. Despite immature coordination of swallowing and breathing, the risk of aspiration is reduced by the high position of the larynx.

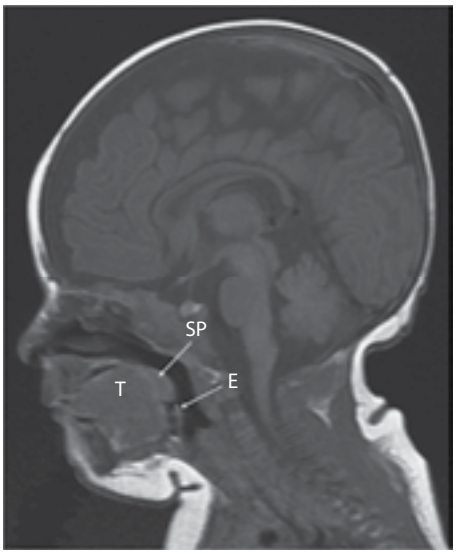


Figure 3.5 Sagittal magnetic resonance image of the upper airway in a newborn. T = tongue, SP = soft palate, E = epiglottis. (Courtesy of Professor Terry Doyle.)

The higher more anterior position of the larynx also means that it is easier to intubate the trachea with a straight-bladed laryngoscope. The narrowest part of the infant's upper airway (about 3.5 mm in a term neonate) is the subglottis at the level of the cricoid cartilage, rather than the vocal cords as in adults. As the infant grows, the larynx descends and the epiglottis loses contact with the soft palate. Gender differences in laryngeal shape and size only begin to appear at about 3 years of age.[26]

Trachea and bronchial tree

The trachea is short, measuring approximately 4–5 cm in length in term neonates[28] and as little as 2–3 cm in premature neonates, making positioning of an endotracheal tube critical. The tip of the tube is usually sited between the clavicles, 1–2 cm above the carina, which corresponds to the vertebral body of T1. As in adults, the trachea starts at the level of the sixth cervical vertebra but bifurcates relatively higher at T3/4 (rather than T4/5 in adults). The trachea is rich in elastic tissue[29] and readily deformable. The right main bronchus is wider and steeper than the left, and the carina is more likely to lie to the left of the midline. Contrary to some reports, an aspirated foreign body is therefore more likely to enter the right lung.[30]

The bronchial tree is developed by the 16th week of intrauterine life; thereafter, conducting airways increase in size but not number.[31] Postnatal lung growth is mostly by alveolar development. Lung volume increases rapidly during infancy. Most alveoli have been formed by 2 years of age and only increase in size thereafter.[32,33] Before the infant

takes its first breath, the terminal bronchioles and alveoli are filled with fluid, mostly produced in the lung. There is more fluid in the lungs of a newborn infant delivered by cesarian section than after vaginal delivery. For the alveoli to expand adequately, surface tension must be reduced; this is achieved by the release of surfactant from type II pneumocytes lining the alveoli. Surfactant also prevents alveolar collapse on expiration, which explains why very premature infants with inadequate surfactant production develop respiratory distress. Remodeling of the pulmonary vessels begins immediately after birth to reduce pulmonary vascular resistance.

Thorax and mechanics of breathing

The neonatal thorax has the shape of a truncated cone and is more rounded in circumference (Figure 3.4). Unlike the adult in whom the compliance of the chest wall and lung are similar, the neonate's chest wall is up to five times more compliant than its lungs.[3] Consequently, it is easily deformable, a fact that is readily apparent in the presence of respiratory distress.

The respiratory rate of a newborn at term is about 40–44 breaths/min. The ribs are more horizontal and contribute less to chest expansion. Infants rely mainly on diaphragmatic breathing. The diaphragm is relatively flat at birth (Figure 3.4) and becomes more dome-shaped with growth. Diaphragmatic contraction tends to pull the ribs inward; concomitant outward movement of the abdomen (thoracoabdominal paradox) is a normal finding in newborns. The work of breathing is greater in a neonate than an adult and still greater in a preterm infant.

The neonatal thymus is large (up to 5 cm wide and 1 cm thick) but variable in size at birth. It is a prominent feature on a chest x-ray (Figure 3.4). The gland overlies the trachea, great vessels (especially the left brachiocephalic vein), and the upper anterior surface of the heart. After the first year of life, it becomes progressively less vascular, and the lymphoid tissue is increasingly replaced by fat.

ABDOMINAL WALL AND GASTROINTESTINAL TRACT

Abdominal and pelvic cavities

The neonatal abdomen is relatively wide and protruberant because the diaphragm is flatter and the pelvic cavity smaller. The distance between the costal margin and iliac crest is proportionately greater in the neonate (Figure 3.4). For these reasons, transverse supraumbilical incisions provide good surgical access. The rectus abdominis muscles may be relatively wide apart in the upper abdomen (divarication); this resolves with growth. The inguinal canal in the newborn is short, measuring about 10–15 mm long in boys.[34–36] It subsequently lengthens with growth.

Compared to an adult, the true pelvis in the neonate is small, both relatively and absolutely, is more circular in cross section, is orientated more horizontally, and has a less pronounced sacral curve. The peritoneal cavity is shallow anteroposteriorly because there is no lumbar lordosis and the paravertebral gutters are poorly developed. The urinary bladder, ovaries, and uterus are all partly intra-abdominal, and the rectum occupies most of the true pelvis (Figure 3.6). The greater omentum is delicate and membranous, rarely extending much below the level of the umbilicus. Indeed, the neonate has altogether less fat in the mesenteries and around the viscera.

Figure 3.6 Midline sagittal section of a plastinated neonatal **(a)** and adult **(b)** female pelvis. Note the relative positions of the bladder (B) and uterus (U), the curvature of the sacrum (S), and the angle of the pelvis (dotted line between sacral promontory and pubic bone [P]). V = vagina, R = rectum. (Courtesy of the W.D. Trotter Anatomy Museum, University of Otago.)

Gastrointestinal tract

At term, the newborn esophagus measures about 8–10 cm in length from cricoid to diaphragm[26]; the upper and lower esophageal sphincters each extend over about 1 cm.[37] Lower esophageal sphincter pressure is particularly low during the first month or two of life. The narrowest part of the upper digestive tract is where the cricopharyngeus muscle blends with the upper esophagus, a potential site of esophageal perforation during the passage of a nasogastric tube.[38]

The anterior surface of the stomach is overlapped by the left lobe of the liver, which extends almost to the spleen. The capacity of the neonatal stomach is 30–35 mL at term but reaches 100 mL by the fourth week. Gastric emptying is relatively slow and poorly coordinated in the first few weeks. The small bowel of the newborn is distributed more horizontally because of the shape of the abdominal cavity. The mean length of the small intestine from the duodenojejunal flexure to the ileocecal junction is around 160 cm when measured at term along its antimesenteric border *in vivo*[39] but considerably longer when measured at autopsy.[40] In normal infants, the duodenojejunal flexure lies to the left of the midline, most often at the level of the L1 vertebra, although this level is variable.[41] The superior mesenteric artery typically lies to the left of the superior mesenteric vein. This vascular relationship is often abnormal in patients with intestinal malrotation, although abnormal orientation of these vessels can be seen in some healthy individuals and a normal relationship may sometimes exist in patients with intestinal malrotation.[42]

The mean *in vivo* length of the colon from the ileocecal junction to the upper rectum is 33 cm at term.[39] The cecum and ascending and descending colon are proportionately shorter than in the adult, and the transverse colon, sigmoid colon, and rectum proportionately longer. The cecum tapers to a proportionately large appendix with a relatively wide orifice. The anal canal has well-defined anal columns and prominent anal sinuses[43]; stasis within these sinuses is a putative cause of perianal sepsis, particularly in male infants.[44]

Neonatal small bowel has few circular folds (valvulae conniventes), and the neonatal colon has no haustra. This makes it difficult to distinguish the small and large bowel on plain abdominal radiographs. Their relative position (central versus peripheral) and caliber are a guide, but a contrast study may be required to accurately differentiate small and large bowel pathology.

Liver and spleen

The neonatal liver weighs about 120 g at term and comprises about 4% of body weight (compared to 2% in the adult); it more than doubles in weight during the first year. The relatively large liver fills much of the upper abdomen. Its inferior border extends 1–2 cm below the costal margin. The premature baby's liver is particularly fragile and vulnerable to injury (e.g., from an abdominal retractor). The neonatal gallbladder is more intrahepatic, and its fundus may not extend below the liver margin.

The tip of the newborn's spleen is often palpable just below the left costal margin. The pancreatic tail is in contact with the spleen, usually at its hilum, in more than 90% of cases, which is a greater proportion than in adults.[45] Accessory spleens are found at autopsy in about 14% of fetuses and neonates as compared to 10% of adults,[46] but it is uncertain whether this is a true increased prevalence.

GENITOURINARY SYSTEM

Genitourinary anomalies are among the commonest congenital malformations, and so it is especially important to understand normal anatomy in the newborn.

Kidneys and suprarenal glands

At birth, the kidneys are about 4–5 cm in length compared to a mean length of 11 cm in adults. Fetal lobulation of the kidneys is still present at birth. Individual nephrons consist of a renal corpuscle with (i) a central glomerulus concerned with plasma filtration and (ii) a renal tubule that produces urine by selective reabsorption of the filtrate. At birth, there are about 1 million renal corpuscles in the cortex of each kidney. Postnatally, cortical nephron mass increases but no new nephrons are made. The glomerular filtration rate (GFR) is low in newborns, particularly in the premature, but in the term infant, the GFR doubles by 2 weeks of age and reaches adult values (120 mL/min per 1.73 m^2) by 1–2 years.[47]

The suprarenal glands are relatively large at birth with a proportionately thick cortex. Their average combined weight is 9 g compared with 7–12 g in the adult. Both glands shrink in the neonatal period.

Bladder and ureter

The bladder is largely intra-abdominal at birth (Figure 3.6) with its apex midway between the pubis and the umbilicus in the unfilled state. Suprapubic aspiration and manual expression of urine are therefore relatively easy. The bladder does not achieve its adult pelvic position until about the sixth year.[3] The intravesical segment of the ureter (intramural and submucosal portions) lengthens from about 0.5 cm in neonates to 1.3 cm (the adult value) by 10–12 years of age. An abnormally short submucosal tunnel predisposes to vesicoureteric reflux (VUR); this type of VUR tends to resolve spontaneously with growth.[48]

Genitalia and reproductive tract

By about the sixth month *in utero*, the testis lies adjacent to the deep inguinal ring connected to the developing scrotum by the gubernaculum. Although the testis originates as a retroperitoneal structure, it is suspended on a short mesentery (mesorchium) within the peritoneal

cavity during abdominal "descent."[49] Inguinoscrotal descent of the testis occurs between 25 and 35 weeks postconception; in this phase, it is invaginated into an elongating peritoneal diverticulum, the processus vaginalis, which subsequently becomes obliterated leaving only the tunica vaginalis around the testis. At term, about 4% of boys have an undescended testis(es); the figure is considerably higher in premature infants. By 3 months of age, the prevalence of cryptorchidism has fallen to 1.5%. The timing and process of closure of the processus vaginalis are both uncertain.[50] Surgical studies have shown that a patent processus vaginalis is present in around 60% of contralateral groin explorations *in infants with a unilateral inguinal hernia* in the first 2 months, falling to around 40% after 2 years of age. Autopsy studies have indicated that the processus is patent in about 80% of newborns, decreasing to about 15%–30% in adults. Boys with cryptorchidism have higher patency rates.

The prostate and seminal vesicles are well developed at birth. The penis and scrotum are relatively large, and the scrotum has a broad base and relatively thick walls. The prepuce begins to separate from the glans *in utero* but is usually only partially retractile at birth.

In baby girls, the ovary lies in the lower part of the iliac fossa and only descends into the ovarian fossa within the true pelvis during early childhood as the pelvis deepens. At birth, the ovaries are relatively large and contain the full complement of primary oocytes, each surrounded by a single layer of follicular cells forming primordial follicles. Of the 7 million oocytes estimated to be present in the female fetus, only 1 million remain at birth, and this number decreases further to approximately 40,000 by puberty.

In the term infant, the uterus is about 3–5 cm long and the cervix forms two-thirds or more of its length (Figure 3.6). Female newborns have a relatively prominent clitoris and labia, and the vagina, which is about 3 cm in length, is relatively thick-walled with a fleshy hymen. After withdrawal of maternal hormones, the uterus and the vagina shrink in size.

MUSCULOSKELETAL SYSTEM

Skull and face

The skull vault is formed by intramembranous ossification, the facial skeleton is derived from neural crest membrane bones, and the skull base and some bony pharyngeal arch derivatives (e.g., hyoid bone and ossicles) by endochondral ossification.[3] During birth, the margins of the frontal and parietal bones are able to slide over each other. In the first 2 days of life, palpable overriding of the bones of the vault is common. However, persistent ridging of suture lines may indicate craniosynostosis. Growth at the coronal suture is mostly responsible for fronto-occipital expansion of the skull; premature fusion causes brachycephaly if bilateral and plagiocephaly if unilateral. Growth at the metopic and sagittal sutures increases skull breadth, the metopic suture fusing at around 18 months of age and the sagittal at puberty. Premature fusion produces the elongated skull of sagittal craniosynostosis, the most common form of craniosynostosis. Premature babies have a tendency to develop a long thin head (dolichocephaly) secondary to postnatal gravitational molding, but this is not due to premature sutural fusion.

Fontanels are formed where several skull vault bones meet. The two most prominent are the anterior fontanel overlying the superior sagittal venous sinus at the junction of the metopic and sagittal sutures (bregma), and the posterior fontanel at the junction of the sagittal and lambdoid sutures (lambda).[51] The size of the anterior fontanel at birth is very variable; if unduly large, it may be an indication of congenital hypothyroidism, raised intracranial pressure or a skeletal disorder.[52] The timing of closure is also variable, but the anterior fontanel is obliterated by 2 years of age in 95% of children[53] and the posterior by 2 months of age.[54]

Postnatal growth of the skull vault is accompanied by disproportionate growth of the facial skeleton and mandible (Figure 3.7). At birth, the bony external ear canal is not developed, and the mastoid process is absent. The facial nerve is therefore more at risk of injury where it emerges from the stylomastoid foramen (e.g., from obstetric forceps). At birth, the two halves of the mandible are united by a fibrous symphysis that fuses in early childhood. The rami are at a more obtuse angle to the body of the mandible. The mandible subsequently changes shape as the teeth erupt and the muscles of mastication and chin develop.

The maxillary and ethmoid sinuses are present at birth, but the sphenoid sinus is poorly developed and the frontal sinuses are absent.[26] The auditory tube is almost horizontal, increasing the risk of middle ear disease; it becomes more vertical during childhood. The hard palate is short, only slightly arched, and ridged by transverse folds, which assist with suckling. The nasolacrimal duct, which drains tear secretions from the conjunctival sac to the inferior meatus of the nasal cavity, is relatively short and wide at birth, but may be obstructed due to incomplete canalization. This can cause excessive tearing, discharge, and infection.

Vertebral column, pelvis, and limbs

The vertebral column in the neonate has no fixed curvatures other than a mild sacral curve. After birth, the thoracic curvature develops first and then, as the infant learns to control its head, sit, stand, and walk, curvatures in the lumbar and cervical spine develop, which help to maintain the center of gravity of the trunk when walking. The sacral promontory "descends" and becomes more prominent. Hemopoiesis occurs in the liver, spleen, and bone marrow in the fetus, but is largely restricted to the bone marrow of the vertebrae, ribs, sternum, proximal long bones, and diploe of the skull after birth.

Of the 800 or so ossification centers in the human skeleton, just over half appear after birth; these include most secondary ossification centers (Figure 3.8). Cartilage is abundant at birth; none of the carpal bones have ossification

(a)

(b)

Figure 3.7 Comparison of a neonatal **(a)** and adult male **(b)** skull. Note the relatively small size of the face and mandible in the neonate, the cranial vault sutures, and the anterior fontanel. Figure 3.8 Bony skeleton of a newborn baby. There are no carpal bones at birth, there are separate ossification centers for the hip, and secondary centers of ossification in the long bones are absent except for the lower end of the femur and upper end of tibia. Specimen prepared by Professor J.H. Scott in 1895. (Courtesy of the W.D. Trotter Anatomy Museum, University of Otago.)

centers. The only secondary centers of ossification in the long bones at birth are in the femoral and tibial condyles and sometimes in the humeral head.[26] The iliac crest, acetabular floor, and ischial tuberosity are all cartilaginous.

The acetabulum is relatively large and shallow at birth and has a characteristic Y-shaped triradiate cartilaginous epiphyseal plate between the ilium, ischium, and pubis. Nearly one-third of the neonatal femoral head lies outside the acetabulum, making the hip joint easier to dislocate. Developmental dysplasia of the hip affects about 1 in 100 live births and is more common in girls. The neonatal femoral neck is short, and the femoral shaft is straight. The proximal femoral growth plate in early infancy is intra-articular so that infection in the proximal femoral metaphysis may cause a septic arthritis. The lower limb muscles in the newborn are relatively underdeveloped, and the gluteal muscle mass is small. The thighs tend to be abducted, flexed, and externally rotated, the knees flexed, and the foot dorsiflexed and inverted. In congenital talipes equinovarus (club foot),

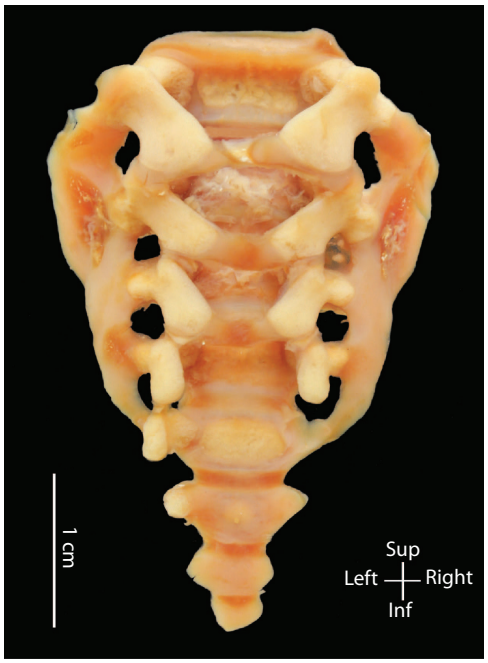

Figure 3.9 Sacrum from a newborn demonstrating the variable development, ossification, and symmetry of the posterior cartilaginous vertebral elements.

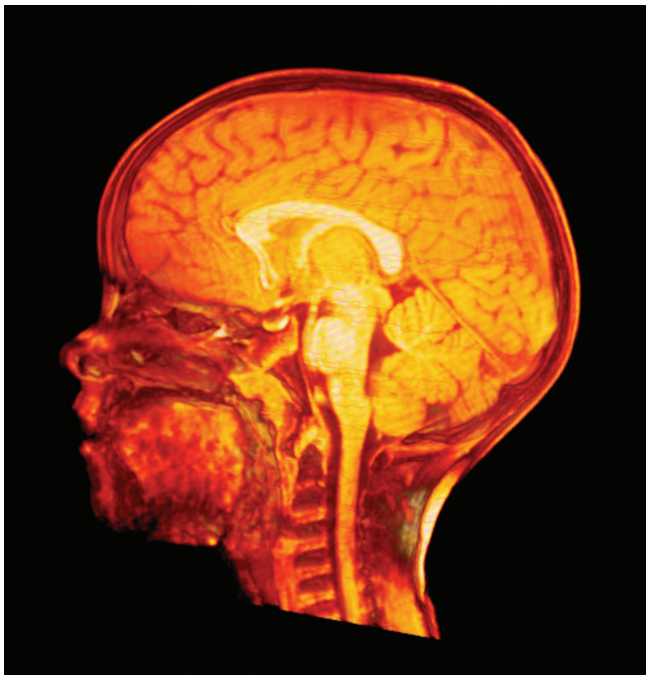

Figure 3.10 3-D volume rendered sagittal MRI scan of the head in an infant.

there is impaired development of the talus causing inversion and supination of the foot and adduction of the forefoot.

Incomplete ossification of the posterior vertebral elements can make palpation of the sacrococcygeal hiatus difficult, increasing the risks of neonatal caudal anesthesia (Figure 3.9).[55] Ultrasound guidance has therefore been recommended when performing this regional block in neonates. Ultrasound has the added advantage of being able to visualize the termination of the dural sac (usually at S2 but at S3 in some), which lies at a variable distance from the sacral cornua.

NERVOUS SYSTEM

At term, the neonatal brain weighs between 300 and 400 g, accounting for about 10% of body weight (compared to 2% in the adult).[26] Brain growth is especially rapid during the first year, when it reaches 75% of its adult volume. The number of neurones is already established at birth, and brain growth is due to an increase in size of nerve cell bodies, further development of neuronal connections, proliferation of neuroglia and blood vessels, and myelination of axons. Myelination is at its peak in the first 6 months of life but continues until maturity.[3] The arrangement of sulci and gyri at birth is similar to the adult, although the central sulcus is slightly further forward and the ventricles are proportionately larger (Figure 3.10). Mean head circumference at term is 34 cm.

The termination of the spinal cord (the conus medullaris) is at a median level of the L2 vertebra in the neonate compared to the lower border of L1 in adults.[56] Variable anatomy means that in some infants, the conus may lie as low as L3; if the conus is unusually low or immobile on a spinal ultrasound scan, spinal cord tethering should be excluded. The supracristal plane between the tops of the iliac crests is slightly higher (L3/4 rather than L4); a lumbar puncture in the newborn should not be performed above this level.

SKIN AND SUBCUTANEOUS TISSUE

Body fat is laid down in the fetus from about 34 weeks' gestation and, with appropriate intrauterine nutrition, increases until term. Plantar fat pads give the neonate a flat-footed appearance. Brown fat is a modified form of adipose tissue concentrated at the back of the neck, in the interscapular region, and in pararenal areas. It is composed of adipocytes with mitochondria that have large and numerous cristae adapted to heat production. However, the neonate's ability to regulate temperature is poorly developed.

At birth, breast tissue is similarly developed in girls and boys. It may appear prominent due to the influence of maternal hormones, even leading to the secretion of a small amount of fluid (witch's milk). Supernumerary nipple(s) may be found along the mammary ridges (milk lines), which extend from the axilla to the groin.

Neonatal skin is relatively thin, but the ability to see peripheral veins is very dependent on the thickness of the subcutaneous tissues. Common sites for peripheral venous cannulation include the dorsal arch veins of the hands and feet; the cephalic vein at the wrist; the cubital fossa; the great saphenous vein immediately anterior to the medial malleolus or behind the medial aspect of the knee; and the superficial temporal vein anterior to the ear. The saphenous,

cephalic and basilic veins are also used for insertion of percutaneous central catheters.

The epidemiology of birth defects

EDWIN C. JESUDASON

BIRTH DEFECTS HELPED DEFINE PEDIATRIC SURGERY

Surgery for birth defects helped create the specialty of pediatric surgery during the middle of the last century. Around this time, pioneering operations were successfully performed to allow the survival of babies with, e.g., esophageal atresia or congenital diaphragmatic hernia (CDH). Indeed, along with innovations such as parenteral nutrition, this concentration of surgical, nursing, and anesthetic expertise now allows high survival rates to be achieved for many previously fatal anomalies. Moreover, for certain conditions that retain high mortality and/or morbidity, fetal surgery represents a promising experimental approach to reduce the harm of birth defects further. Given this progress, it would be tempting to imagine that the problem of birth defects was largely solved.

BIRTH DEFECTS REMAIN POTENT CAUSES OF INFANT MORTALITY AND LONG-TERM DISABILITY

The advances made against infectious disease mean that birth defects represent a leading cause of infant mortality. This holds true in nations with expensive healthcare systems and indeed anywhere that infant mortality has fallen below ~50 per thousand births.[1] Prevention is possible for some of these birth defects: congenital rubella syndrome might be eradicated by an effective program of maternal immunization[2]; a subset of neural tube defects continue to occur due to inadequate implementation of preconceptual folate prophylaxis.[3,4] However, for many defects, prevention is not always possible, feasible, or effective. In these circumstances, the epidemiological challenge extends from new problems like the Zika outbreak to explaining the changed prevalence of familiar defects like gastroschisis (Figure 4.1).[5,6] Hence, birth defects will continue to cause not only infant deaths but also premature birth and chronic disability. Pediatric services have tended to focus on perinatal approaches to birth defects, but it is clear that the needs of long-term survivors have to be considered more fully. For example, the transition toward independent adulthood poses particular challenges. While it is tempting to attribute this to the patients and their families, it is striking how the separate development of pediatric and adult specialists means that there is often a lack of meaningful engagement between the two realms. An upshot is that children and young adults are often "held back" within children's services only then to be ejected belatedly into an adult realm that seems disjointed and unfamiliar. It is likely that pediatric surgeons can do more to address this transition and to cater to the needs of survivors via greater attention to patient-derived outcomes and Engel's biopsychosocial model of health.

BIRTH DEFECT EPIDEMIOLOGY AND TERATOLOGY EMERGED FROM OUTBREAK INVESTIGATION

Like neonatal surgery, teratology and birth defect epidemiology really date from only the mid–twentieth century. Key historical developments include the recognition of congenital rubella syndrome (noted by clinical ophthalmological examination) and the thalidomide disaster (phocomelia and other defects associated with maternal thalidomide administration for morning sickness).[7,8] These chastening episodes illustrated the devastating consequences of prenatal infection and drug exposure respectively. They highlighted the need to formalize birth defect surveillance. Today, this serves a range of important purposes. These include early warning of outbreaks, identification of potential causes, planning neonatal services, informing prenatal counseling, and the comparison of outcomes (as a guide toward best practice).[9]

Figure 4.1 Gastroschisis—birth defect prevalences can change. Data from birth defect registries indicate an increase in gastroschisis prevalence. It remains to be seen if the severity of gastroschisis is also increasing: in this severe and unusual example, in addition to the gut, the liver (arrowed) lies outside the neonatal abdomen. Furthermore, the thorax is narrowed; this child needed ventilation immediately from birth. (Image used courtesy of the author.)

CAUSATION OF BIRTH DEFECTS REMAINS OFTEN COMPLEX AND UNCERTAIN

Before considering the methods of birth defect surveillance, it is worth sketching out the developmental biology that underpins birth defects.[10] Causes of birth defects can be considered as parental, fetal, and environmental. In reality, they will often overlap. For example, grandparental behaviors (or exposures) may produce epigenetic modifications that only manifest themselves in the developing fetus.

A familiar example of a parental factor is the impact of maternal age on Down's prevalence.[11] Alternatively, maternal diseases such as diabetes are well-described risk factors for birth defect formation.[12] The role of paternal age and/or exposures is more difficult to quantify.[13] Fetal causes might include genetically determined inborn errors of metabolism such as those causing intersex anomalies in congenital adrenal hyperplasia, chromosomal lesions such as Edwards' etc., and twinning (with its increased risk of birth anomalies). Environmental causes include those related to prenatal drug exposure (alcohol, smoking, illicit drugs, thalidomide, valproate, phenytoin, warfarin, etc.) as well as the impact of intrauterine infections (e.g., toxoplasmosis, rubella, cytomegalovirus, possibly Zika).[14–16] The impact on birth defect prevalence of assisted reproductive technologies such as in vitro fertilization and intracytoplasmic sperm injection is quite difficult to assess.[17] The suggestion that anomaly rates are higher in assisted pregnancies needs to contend with confounding factors, e.g., the increased rates of multiple pregnancy and parental differences that may have created the need for assisted reproduction. Environmental contributors to birth defects may also include *endocrine disruptors*: these estrogenic compounds are conjectured to contribute to anomalies of sexual development in fetal males (e.g., hypospadias) as well as putative impairment of adult male sperm quality.[16] In light of such difficulties in attributing cause, it is simpler to admit that only the minority of birth defects are known to arise from a simple genetic or environmental cause. At present, the remainder appear to have multifactorial origins. In such circumstances, it is helpful to consider birth defect causation as the result of complex interactions between genes and environment. Hence, cases of spina bifida may result from micronutrient deficiency in the context of predisposing enzyme polymorphisms.[18] Similarly, teratogenic drugs may interact with pharmacogenomic predispositions to help explain why only certain pregnancies are affected.[19] Beyond considerations of even complex causation, it remains likely that simple chance has a major role to play (similar to the stochastic effects noted in radiation biology).[20]

BIRTH DEFECTS APPEAR TO ARISE TYPICALLY (BUT NOT EXCLUSIVELY) IN THE FIRST TRIMESTER

Developmental biologists refer to *competence windows* to describe periods in development when particular cells and tissues are capable of responding appropriately to certain growth and transcription factors.[21] In a similar manner, developing organs are contended to have particular temporal windows when an otherwise nonspecific teratogenic stimulus will impact disproportionately on formation of that organ system. During the first trimester, organ morphogenesis predominates, while later trimesters are devoted to organ growth and maturation. Unsurprisingly, therefore, sensitivity to teratogens is held to peak during the first trimester. Hence, pregnant women are advised to avoid medications during this part of gestation in particular. Teleologically, morning sickness, which peaks during the first trimester, is postulated to help reduce ingestion of potential teratogens during this period of maximum vulnerability. While the model of first-trimester teratogenesis appears appropriate for many birth defects, certain anomalies appear to arise later as a result of fetal events, e.g., amniotic band formation, intussusception, or vascular accident. Gastroschisis and intestinal atresiae may be considered in this latter category.[22–24] Indeed, the contrast between exomphalos and gastroschisis in terms of associated anomalies (and hence prognosis) may be explained by the different times they are held to originate in development. Exomphalos is considered an embryonic lesion that is accompanied by contemporaneous lesions of organogenesis

in other systems such as the heart. In contrast, gastroschisis is thought to result from a discrete fetal vascular accident (like the associated intestinal atresiae) and to lack extraintestinal manifestations as a consequence. An alternative view, however, is that intestinal atresiae result only rarely from fetal accidents such as intussusception and are in fact better understood as failures of mesenteric vascular development.[25]

A contrast between duodenal atresia and small bowel atresia may likewise be understood as the result of their differing onsets and etiologies. Duodenal atresia was historically explained as an embryonic failure of luminal recanalization; although this "solid core" theory has been contradicted by more recent animal studies, the association between duodenal atresia and other defects (e.g., cardiac lesions, esophageal atresia, and Down's syndrome) supports an embryonic origin of this malformation.[26,27] In contrast, small bowel atresiae are claimed to follow mesenteric vascular occlusion usually in fetal life.[28] Aside from gastroschisis, intestinal atresiae are unlikely to be associated with other structural lesions.

Between these two "extremes" are birth defects where an embryonic lesion has deleterious knock-on effects later in fetal development. Based on experimental models, the neurological sequelae of spina bifida are postulated to result not only from the primary failure of neural tube closure but also from consequent exposure of the neural placode to amniotic fluid.[29] Similarly, lung hypoplasia in CDH may emerge as an embryonic lesion prior to CDH only for compression by the visceral hernia to exacerbate the pulmonary lesion.[30] In circumstances such as these, where the pathology is thought to progress during fetal life, prenatal surgical correction has been a logical proposal to meet the challenge of refractory mortality and morbidity.[31]

CLASSIFICATION OF BIRTH DEFECTS FOR EPIDEMIOLOGICAL PURPOSES

Birth defect epidemiology involves the registration of anomalies by type. At present, birth defect registries such as EUROCAT (European Surveillance of Congenital Anomalies) use a classification scheme based around organ systems (see Table 4.1), specific diagnoses, and International Classification of Diseases codes (see Table 4.2: both tables are derived from data published by EUROCAT at http://www.eurocat-network.eu/accessprevalencedata/prevalencetables). Cooperation between registries helps by pooling data and also by building consensus on, e.g., exclusion of minor anomalies without major and/or long-term sequelae (e.g., cryptorchidism or congenital hydrocele) or, e.g., how abnormalities of gut fixation in CDH might be recorded. Although anomalies are currently classified by structural anomaly (e.g., CDH, esophageal atresia) or defined diagnosis (e.g., Down's), it is likely that in the future, anomalies may be classified or at least subgrouped by genotypic differences rather than anatomic details alone. Such distinctions may be prognostically and therapeutically important: e.g., exomphalos in the context of Beckwith–Wiedemann syndrome is associated with the additional hazards of hypoglycemia, macrosomia, and increased tumor risk due to disordered gene imprinting.[32] Hence the anatomic defect (exomphalos) becomes less important than the genetics and its multisystem sequelae. Similarly, it is postulated that subgroups of spina bifida may be folate resistant due to underlying genetic/enzymatic variation.[18,33] The design of preconceptual prophylaxis for birth defects may need to acknowledge pharmacogenomically distinct subgroups to avoid benefits within one subgroup being overlooked due to a surrounding nonresponder cohort.

Table 4.1 Birth prevalence of malformations in 2008–2012 grouped by EUROCAT category

Organ system	Live birth + fetal death + termination/10,000 births (to 2 s.f.)
All	260
Congenital heart disease	82
Limb	41
Chromosomal	39
Urinary	34
Nervous system	25
Genital	22
Digestive system	19
Orofacial clefts	14
Abdominal wall defects	6.5
Genetic syndromes + microdeletions	5.0
Respiratory	4.1
Eye	4.2
Ear, face, neck	2.0
Teratogenic syndromes with malformations	1.4

Note: Rates for each category are inclusive of cases with chromosomal lesions and derived from registries with full EUROCAT membership.
Abbreviation: s.f. = significant figures.

Having a system of classification is only part of the task. Notification and classification are subject to local variations in practice. When resources exist for expert-mediated classification of birth defects by diagnosis, this approach to birth defect epidemiology appears the best currently available.[34] However, even some North American registries lack clinician input in the classification/assignment of observed birth defects. The impact of this omission on data quality remains to be determined. In the contrasting circumstances of rural China, expert-led assignment of cases has been substituted with simple photographic recording of malformations: this system allows the registry to function but also allows difficult cases to be assigned later after remote assessment of images by experts.[35] In addition, the photographs

Table 4.2 Birth prevalence of malformations of relevance to pediatric surgery (2008–2012) grouped by diagnosis from registries with full EUROCAT membership

Anomaly	Live birth + fetal death + termination/10,000 births
Down's	23
Hypospadias	18
Congenital hydronephrosis	11
Edwards'	5.4
Spina bifida	4.9
Anorectal malformations	3.2
Exomphalos	3.1
Diaphragmatic hernia	2.8
Gastroschisis	2.8
EA/TOF	2.6
Duodenal atresia/stenosis	1.4
Hirschsprung's disease	1.3
Bilateral renal agenesis	1.2
CCAM	1.1
Intestinal atresia/stenosis	0.92
Posterior urethral valves/ prune belly	0.89
Bladder extrophy/epispadias	0.71
Situs inversus	0.68
Indeterminate sex	0.67
Amniotic band	0.51
Biliary atresia	0.31
Conjoined twins	0.18

Note: Rates for each category are inclusive of cases with chromosomal lesions. These are birth prevalences (including fetal death/terminations) and not the prevalences experienced at pediatric surgical units.

Abbreviations: CCAM = congenital cystic adenomatoid malformations, TOF = tracheo-oesophageal fistula.

potentially allow the classifiers to calibrate their judgments against those from other registries.

COUNTING OF BIRTH DEFECTS IS AFFECTED BY THE DEFINITION OF STILLBIRTH

Birth defect epidemiology becomes difficult whenever the classification of defects is not uniform or straightforward. However, an equal challenge remains the counting of birth defects. This task is complicated by practical barriers to case ascertainment (e.g., inadequate resources), the definition of stillbirth, and the effects of prenatal diagnosis and terminations.

Recording of anomaly prevalence lies at the core of birth defect epidemiology. To account for the unknowable incidence of a defect amongst vast numbers of naturally miscarried pregnancies, epidemiologists measure the prevalences of defects within a defined birth cohort: i.e., the number of live and stillborn cases of the defect, as a proportion of all births (live and stillborn). This definition depends on the artificial distinction between miscarriage and stillbirth: EUROCAT's recommendation is that spontaneous pregnancy losses prior to 20 weeks' gestation are counted as miscarriages (and do not contribute to anomaly prevalence), while similar losses at 20 weeks of gestation and beyond are counted as stillbirths (and included in prevalence statistics). Despite these guidelines, several countries have established different demarcations (e.g., 24 or 28 weeks or even 500 g weight). Clearly, some estimate of prenatal birth defects is required to avoid seriously underestimating overall prevalences.[36] However, the demarcation of stillbirths begins to complicate matters. Countries using later gestational cutoffs may underestimate birth defect prevalence compared to registries where 20 weeks is used. Hence, minor changes in convention can lead to large but artificial differences in anomaly prevalence.

While a definition of stillbirths is needed for data collection, the sharp demarcation (whether 20 weeks or later) also appears arbitrary from a biological perspective. Consider, a hypothetical prenatal medical therapy that reduces the prevalence of a specific birth defect. When the anomaly is rare (as most are), it may be difficult to determine whether an observed reduction in prevalence is truly due to fewer malformations or instead due to the promotion of earlier loss of affected pregnancies (i.e., prior to the 20th week or other agreed-upon margin). This latter phenomenon, termed *terathanasia*, has been invoked to explain how folate supplementation might influence the prevalence of neural tube defects.[37]

PRENATAL DIAGNOSIS: THE GREATEST CHALLENGE TO BIRTH DEFECT EPIDEMIOLOGY?

The classification of birth defects and the definition of stillbirth make anomaly surveillance complex. However, the impact of prenatal diagnosis is arguably more important still. Prenatal diagnosis (in particular, nonspecific ultrasound screening) confounds birth defects surveillance in a number of ways:

1. Prenatal diagnosis increases identification of birth defects within the cohort of assessment by diagnosing those who may otherwise have perished prenatally (and were uncounted), or those who may have presented beyond the neonatal period (if at all). Consider prenatal identification of cystic lung lesions. Some would never have been diagnosed (either regressing spontaneously or persisting asymptomatically). Others would have presented later (beyond the scope of the birth defects registry).
2. Prenatal diagnosis alters antenatal management and results in terminations (or fetal intervention), which affects the numbers of birth defects being counted. Most registries try to keep data on terminations for birth

defects, but these data are hard to find when terminations are prohibited by law.
3. Prenatal diagnosis may be inaccurate and unchecked. Pathological verification after termination may be incomplete or absent, yet the presumptive "diagnosis" is included in the birth defect tally.
4. The resources and expertise to perform prenatal sonography vary with location (thereby hampering international comparison of birth defect prevalences).

In summary, the apparently simple task of counting live and stillborn cases for birth defect surveillance is fraught with difficulty once (1) the arbitrary definition of stillbirth is imposed and (2) ubiquitous prenatal imaging prompts both terminations and identification of previously occult "cases."

Given these challenges in data collection, epidemiologists are aided by being able to compare a variety of surveillance databases. Many European registries are incorporated into the EUROCAT initiative. Similarly, several other registries feed into birth defect surveillance data furnished by the World Health Organization (WHO). Their *Birth Defects Atlas* is an interesting publication available in the public domain (http://www.who.int/nutrition/publications/birthdefects_atlas/en/). Most importantly it is instructive to read and consider the caveats that EUROCAT and WHO place upon their data. Their caveats not only highlight the problems discussed in the previous sections but also allude to the ongoing challenge of inadequate resources and expertise for birth defect reporting. This in turn impairs the data accuracy and may help explain insufficient action upon findings. Major studies reinforce the logistical shortcomings of birth defect reporting in the United Kingdom.[38]

PEDIATRIC SURGEONS OFTEN FOCUS ON THEIR INSTITUTIONAL SERIES OF BIRTH DEFECTS

Small institutional series are the staple of pediatric surgeons' reporting. But several studies have shown how institutional series are vulnerable to bias and confounding.[39–41] Indeed, these studies face broader problems than population-based registries. Ascertainment remains a particular issue. For example, prenatal diagnosis, terminations or pretransfer deaths can each foster an impression that the institution is improving its outcomes when, in fact, extramural changes are responsible. Moreover, surgeons try to stratify for disease severity to show that their (good) results are not simply the product of a low-risk caseload (Figure 4.2). But it can be misleading to use the frequency of interventions to stratify for severity in a birth defect cohort. For example, in CDH, the decision to patch and/or use extracorporeal membrane oxygenation (ECMO) and/or nitric oxide may owe more to institutional protocols than differences in pathophysiology between cases.

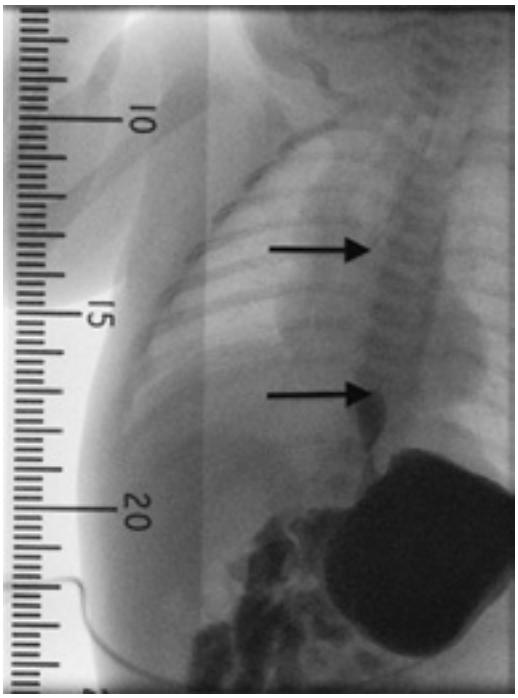

Figure 4.2 Birth defect registries and disease severity. Birth defect registries generally do not distinguish anomaly severity (despite implications for service provision and outcome measures). This gap assessment x-ray for pure esophageal atresia (EA) shows the tip of the oral tube pressed down (upper arrow) and refluxed contrast in the distal pouch (lower arrow). Treated by the author with a single-stage "Bax" jejunal interposition at 7 weeks of age, this anomaly is registered just like the more common EA with distal fistula, despite the very different management and resources required.

A "LIFE-COURSE" APPROACH TO BIRTH DEFECTS

Given the aforementioned caveats, where can pediatric surgery make progress? Advances in prenatal imaging may improve prenatal prognostication and case selection for fetal therapies.[42] But better imaging may also identify more "defects" of questionable significance. To help families balance these developments, pediatric surgeons will need to keep abreast of birth defect epidemiology and to collaborate with other specialties. A larger prize may be realized if pediatric surgery follows epidemiology in widely adopting "life-course" studies to assess the impact over time of correcting birth defects surgically. Embracing a life-course approach means that, like pediatric oncology, further thought and training can be focused on the needs of teenage and young adult (TYA) survivors. Pediatric surgery can also adopt the biopsychosocial model and the creative, problem-solving approach exemplified by, e.g., trauma rehabilitation. These efforts may help the team broach issues well before the hurdles of transitional care. It may also allow such issues to be addressed using the full breadth of nonsurgical, nonpharmacological approaches.

Prenatal diagnosis of surgical conditions

N. SCOTT ADZICK

INTRODUCTION

Prenatal diagnosis has undergone an explosion of growth in the past two decades. The primary impetus for this rapid expansion has come from the widespread use of prenatal ultrasonography. Most correctable malformations that can be diagnosed in utero are best managed by appropriate medical and surgical therapy after maternal transport and planned delivery at term. Prenatal diagnosis may influence the timing (Table 5.1) or the mode (Table 5.2) of delivery, and in some cases, may lead to elective termination of the pregnancy. In rare cases, various forms of in utero therapy may be possible (Table 5.3).

Prenatal diagnosis has defined a "hidden mortality" for some lesions such as congenital diaphragmatic hernia (CDH), bilateral hydronephrosis (HN), sacrococcygeal teratoma (SCT), and cystic hygroma. These lesions, when first evaluated and treated postnatally, demonstrate a favorable selection bias. The most severely affected fetuses often die in utero or immediately after birth, before an accurate diagnosis has been made. Consequently, such a condition detected prenatally may have a worse prognosis than the same condition diagnosed after delivery.[1] Multidisciplinary care and nondirective counseling are the crux of appropriate prenatal management of most congenital anomalies. The perinatal management of the patients involves many different medical disciplines, including obstetricians, sonographers, neonatologists, geneticists, pediatric surgeons, and pediatricians. It is essential that the affected family be managed using a team approach, and that information and experience be exchanged freely.

In this chapter, we will discuss the prenatal diagnosis of neonatal surgical conditions. First, a brief summary of the diagnostic methods currently available will be given. Then a review of prenatal diagnosis by organ system will be presented.

ULTRASOUND

Ultrasound testing has become a routine part of the prenatal evaluation of almost all pregnancies. It is especially important to perform ultrasound for pregnancies with maternal risk factors (e.g., age over 35 years, diabetes, previous child with anatomic or chromosomal abnormality) and if there is an elevation in maternal serum alphafetoprotein (MSAFP). Most defects can be reliably diagnosed in the late first or early second trimester by a skilled sonographer. Early in gestation, nuchal translucency measurements are an independent marker of chromosomal abnormalities, with a sensitivity of about 60%.[2] This abnormality may be detected on transvaginal ultrasound at 10–15 weeks gestation, thus providing an early test for high-risk pregnancies. Nuchal cord thickening may also be a marker for congenital heart disease[3] and may be a valuable initial screen to detect high-risk fetuses for referral for fetal echocardiography. It is important to remember that sonography is operator-dependent; the scope and reliability of the information obtained are directly proportional to the skill and experience of the sonographer.

MAGNETIC RESONANCE IMAGING

Until recently, the long acquisition times required for magnetic resonance imaging (MRI) were not conducive to fetal imaging because fetal movements resulted in poor quality images. Obtaining adequate images with the traditional spin-echo techniques required fetal sedation or paralysis.[4] With the development of ultrafast scanning techniques, the artifacts caused by fetal motion have almost been eliminated.[5] While fetal MRI is most commonly used to evaluate the fetal central nervous system, the ability to obtain cross-sectional imaging has made this tool a crucial adjunct to ultrasound for many pediatric surgical diseases, including

measurement of lung sizes in CDH and evaluation of airway anatomy in neck masses. This technique is now an important part of prenatal evaluation of fetuses referred to our institution and has greatly enhanced our ability to diagnose and treat fetal malformations.

AMNIOCENTESIS

The first report of the culture and karyotyping of fetal cells from amniocentesis was by Steele and Berg[6] in 1966. Since then, it has become the gold standard for detecting fetal chromosomal abnormalities by karyotyping. It is usually performed at 15–16 weeks gestation and involves a very low risk of fetal injury or loss. Attempts at early amniocentesis (11–12 weeks gestation) have been complicated by a higher pregnancy loss, increased risk of iatrogenic fetal deformities, and increased post-amniocentesis leakage rate.[7] For this reason, the most reliable method for first trimester diagnosis remains chorionic villus sampling (CVS). In addition to screening for the most common chromosomal abnormalities using karyotyping, modern sequence analysis and microarrays have revolutionized our ability to detect small deletions or duplications that are not apparent with karyotyping.[8]

CHORIONIC VILLUS SAMPLING

CVS may be performed at 10–14 weeks gestation and involves the biopsy of the chorion frondosum, the precursor for the placenta. Either a transcervical or transabdominal approach may be used, both under ultrasound guidance. The cells obtained may be subjected to a variety of tests including karyotype, microarray, or enzymatic activity. Due to the high mitotic rate of the chorionic villus cells, results for karyotyping may be obtained in less than 24 hours. Disadvantages include diagnostic errors due to maternal decidual contamination or genetic mosaicism of the trophoblastic layer of the placenta. When performed by experienced operators, the pregnancy loss rate is equivalent to second trimester amniocentesis.[8]

BIOCHEMICAL MARKERS

Maternal blood and amniotic fluid can be screened for the presence of various biochemical markers that indicate fetal disease. About two-thirds of women in the United States currently undergo screening for Down's syndrome and other chromosomal abnormalities with the "triple test," which includes measuring serum alpha-fetoprotein with human chorionic gonadotropin and unconjugated estriol.[9] This screening is performed in the early second trimester, and the detection rate for Down's is 69%, with a 5% false positive test.[10] A positive result on the serum screening test indicates a need for chromosome analysis by amniocentesis.

PERCUTANEOUS UMBILICAL BLOOD SAMPLING

Umbilical venous blood can also be used to determine the karyotype and diagnose various metabolic and hematological disorders. The procedure for obtaining it is performed at around 18 weeks gestation under ultrasound guidance. Karyotype results may be obtained within 24–48 hours. In various large series, the mortality from the procedure has been reported to be 1%–2%, with increasing mortality with long procedure times and multiple punctures.[11–13]

FETAL CELLS IN THE MATERNAL CIRCULATION

Since the advent of fluorescence-activated cell sorting, there has been growing interest and progress in detecting circulating fetal cells or cell-free nucleic acids in maternal blood

Table 5.3 Diseases amenable to fetal surgical intervention in selected cases

Malformation	Effect on development	In utero treatment
Congenital diaphragmatic hernia	Pulmonary hypoplasia, pulmonary hypertension	Tracheal occlusion and release
CCAM or BPS	Pulmonary hypoplasia, hydrops	Thoracoamniotic shunting, lobectomy, maternal steroids
SCT	Massive arteriovenous shunting, placentomegaly, hydrops	Excision
Urethral obstruction	HN, renal dysplasia, lung hypoplasia	V-A shunting, laser ablation of PUV
MMC	Damage to spinal cord, paralysis	Closure of defect

for diagnostic purposes.[14] While the number of intact cells in the circulation is limited, amplification of fetal cell–free nucleic acids using real-time PCR has growing utility in early prenatal diagnosis.[15] Fetal DNA can be detected reliably by 9 weeks and increases with gestational age.[16] This method can be used for gender determination in the first trimester (if Y chromosome sequences are found, the fetus is male and if not, assumed to be female) and can thus be helpful in counseling for X-linked disorders. Rhesus factor determinations are also accurate and can avoid unnecessary treatment of an Rh negative mother if the fetus is also negative. In the future, it may be expanded to detecting paternally inherited single gene mutations. Noninvasive prenatal testing is becoming the routine screening test for prenatal diagnosis of aneuploidies.

PRENATAL DIAGNOSIS OF SPECIFIC SURGICAL LESIONS

Neck masses

Prenatal diagnosis and surgical management can be lifesaving for fetuses with airway obstruction. Fetal airway obstruction could be a result of extrinsic compression of the airway by lesions such as cervical teratoma or cystic hygroma, or intrinsic defects in the airway such as congenital high airway obstruction syndrome (CHAOS). Although large congenital neck masses causing airway obstruction previously carried an enormous perinatal mortality,[17] the advent of the ex utero intrapartum treatment (EXIT) procedure[18,19] has improved their outcome by providing a means of controlling the airway during delivery and converting an airway emergency into an elective procedure (Figure 5.1).

Cystic hygroma diagnosed in utero is a severe diffuse lymphatic abnormality, which is frequently associated with hydrops, polyhydramnios, and other abnormalities.[20] Chromosomal abnormalities are very common (62% overall), with the most common being Turner's syndrome.[21] There are two groups of prenatally diagnosed cervical lymphangiomas: those diagnosed in the second trimester are usually in the posterior triangle of the neck, have a high incidence of associated abnormalities, and carry a very poor prognosis.[22] Those diagnosed later in gestation are most often isolated lesions and generally do not lead to hydrops. Hydrops is an ominous finding in fetuses with cystic hygroma,[17] as is the presence of aneuploidy and septations in the mass.[23] However, fetuses with normal karyotype, nonseptated masses, and no evidence of hydrops may have a good prognosis.[24] Therefore, it is important to monitor the fetus for development of hydrops by serial evaluations.

Figure 5.1 EXIT procedure for giant neck mass.

Teratomas are asymmetrical lesions that are frequently unilateral, with well-defined margins. They may also be multiloculated, irregular masses with solid and cystic components. Most teratomas contain calcifications. Some fetuses with huge cervical teratomas may also have severe pulmonary hypoplasia with its attendant morbidities, and this possibility should be addressed during prenatal counseling.[25] MRI is a very useful adjunct to ultrasound in evaluating giant neck masses. We have used it successfully for showing the relationship of the mass to the airway in preparation for the EXIT procedure.[26] T1 weighted images may help differentiate teratomas from lymphangiomas.[27]

The EXIT procedure, originally designed for removal of tracheal clips in patients with CDH,[18] has proven lifesaving for many fetuses with giant neck masses.[19,28,29] This procedure involves performing a maternal hysterotomy using the uterine stapling device and obtaining control of the fetal airway while the fetus remains on placental support. In order to prevent uterine contractions during the procedure, the mother is given inhalational anesthetic and tocolytics, warm saline is infused through a level I device, and only the head and shoulders of the fetus are delivered. After attaching a pulse oximeter to the fetal hand to monitor heart rate and oxygen saturation, direct laryngoscopy and, if possible, endotracheal intubation are performed. If the airway cannot be secured in this way, a rigid bronchoscope is inserted to determine the anatomy. If secure airway establishment is still unsuccessful, a tracheostomy can be performed. After securing the airway, surfactant is administered for premature fetuses, the cord is clamped, and the infant is taken to an adjacent operating room for resuscitation and possible immediate resection of the mass. In our most recent review of the EXIT procedure,[28] establishment of a reliable airway was highly successful.

The EXIT procedure has also been useful in the perinatal resuscitation of fetuses with a range of anomalies expected to cause hemodynamic compromise at birth, such as giant lung masses (EXIT to congenital cystic adenomatoid malformation [CCAM] resection),[30] CHAOS,[31] severe congenital heart disease with CDH (EXIT to extracorporeal membrane oxygenation [ECMO]),[32] and even thoracopagus conjoined twins with a single functioning heart.[33] The most critical component of the EXIT procedure is deep inhalational anesthesia, which maximizes uteroplacental blood flow to avoid fetal hypoxia. It is therefore different from a Cesarean

section and carries the risk of significant maternal blood loss if there is not careful coordination between the surgical and anesthetic teams.[34]

SACROCOCCYGEAL TERATOMA

SCT is the most common newborn tumor, occurring in 1/35,000 to 40,000 of births.[35] The AAPSS classification[36] defines four types with differing prognoses: Type 1 tumors are external, with at most a small presacral component, and carry the best prognosis. Type 2 tumors are predominantly external with a large intrapelvic portion. Type 3 lesions are predominantly intrapelvic with abdominal extension with only a minor external component. Type 4 lesions are entirely intrapelvic and abdominal. The latter have the worst prognosis since they are difficult to diagnose, sometimes less amenable to surgical resection, and frequently malignant at the time of diagnosis because of the delay in diagnosis. Overall, prenatally diagnosed SCT has a worse prognosis than those diagnosed at time of birth.

On prenatal ultrasound, SCT appears as a mixed solid and cystic lesion arising from the sacrum. The tumor frequently contains calcifications. Since there is acoustic shadowing by the fetal pelvic bones, it is not always possible to determine the most cephalad portion of the tumor by ultrasound. Ultrafast fetal MRI may determine the intrapelvic dimensions of the tumor, spinal canal involvement, and the presence of hemorrhage (Figure 5.2).[37,38] Those fetuses with mainly solid and highly vascular SCT have a higher risk of developing hydrops.[39,40] High output cardiac failure is the result of the hemodynamic effects of the large blood flow to the tumor,[41,42] and anemia from hemorrhage into the tumor may compound this problem. In severe cases, the mother with placentomegaly develops "mirror syndrome," a severe preeclamptic state with vomiting, hypertension, proteinuria, and edema. This phenomenon may be mediated by the release of vasoactive compounds from the edematous placenta. As with other fetal masses, the development of hydrops is a grave sign, with almost 100% mortality without fetal intervention.[43,44]

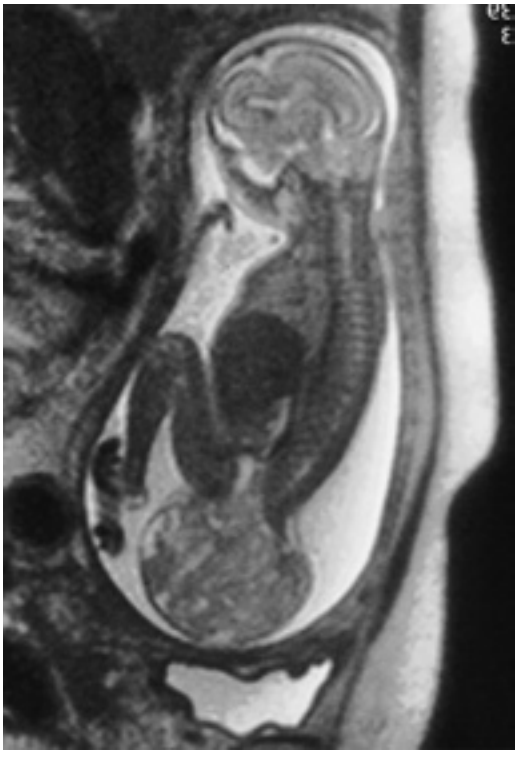

Figure 5.2 MRI of a large SCT.

The prediction of which fetuses with SCT are at highest risk for developing hydrops is therefore the crucial issue in prenatal management. A thorough prenatal evaluation with US, MRI, and fetal echocardiography is important in defining such a group. In a series of 23 cases seen at Children's Hospital of Philadelphia (CHOP) between 2003 and 2006,[45] we observed that rapid tumor growth (>150 cm^3/week) identifies a group of fetuses with a higher risk of prenatal mortality. The combined cardiac output correlates with tumor growth, with those fetuses >600 mL/kg/min portending a higher risk of complications. The solid component of the mass is an important prognostic indicator—when the solid tumor volume is normalized to the head volume, fetuses with a ratio <1 all survive, whereas those with a volume >1 have 61% mortality.[46] A similar classification scheme based on size, growth, and vascularity has also been reported.[47]

Prenatal interventions for SCT include cyst aspiration (for those with a dominant cystic component), amnioreduction (for those with severe, symptomatic polyhydramnios with an AFI >35), amnioinfusion (for those with bladder outlet obstruction, to facilitate placement of a vesioamniotic shunt), or open fetal surgery for resection of the mass. The latter option should only be considered for fetuses with impending high-output failure, rapid growth, type I lesion amenable to resection, and gestational age between 20 and 30 weeks. Since our initial report of the first successful case of fetal SCT resection in 1997,[48] we have had seven additional cases, with five survivors.[49] It is important to note that the purpose of fetal resection is debulking and interruption of the "vascular steal," and a complete resection is performed postnatally. Minimally invasive prenatal interventions such as laser vessel ablation, radiofrequency ablation, and alcohol sclerosis have been reported for the management of hydropic fetuses with virtually no success, and thus these approaches should be abandoned.[50] For fetuses older than 28 weeks and impending hydrops, emergent delivery with immediate postnatal resection should be considered. The combined perinatal mortality from both of our published series is 43% (19/44) excluding terminations,[45] illustrating the severity of this disease.

CONGENITAL CHEST LESIONS

CCAM and bronchopulmonary sequestration

CCAM represents a spectrum of disease characterized by cystic lesions of the lung.[51] Macrocystic lesions are larger

than 5 mm in diameter and may be solitary cysts that grow to several centimeters (Figure 5.3). Microcystic disease has multiple cystic lesions less than 5 mm in diameter. Prenatal ultrasound can generally distinguish individual cysts in macrocystic disease, while microcystic lesions usually have the appearance of an echogenic, solid lung mass.[52] Bronchopulmonary sequestration (BPS) is an aberrant lung mass that is nonfunctional and usually has a systemic blood supply. The two lesions may be related embyrologically, with many reported cases of hybrid lesions that have CCAM-like architecture and a systemic blood supply.[53,54] Some of these lesions may decrease in size during fetal life,[55] but postnatal evaluation is still warranted to detect residual disease for resection[56] because of the risk of pulmonary infections and the development of tumors such as pleuropulmonary blastoma.

MRI is useful in delineating normal lung from abnormal.[57] In CCAM, the number and size of cysts contribute to the signal intensity on T2-weighted images.[5] MRI can also define BPS from surrounding lung due to its high signal intensity and homogeneous appearance.[57] Ultrasound with color flow Doppler is more accurate in demonstrating systemic feeding vessels. MRI may also be helpful in making the correct diagnosis in cases where ultrasound is ambiguous. In a series of 18 lung lesions that were viewed with both ultrasound and MRI, multiple chest abnormalities were misdiagnosed as CCAM on the ultrasound, including CDH, tracheal atresia, pulmonary agenesis, neurenteric cyst, bronchial stenosis, and BPS.[57] MRI helped establish the correct diagnosis in these cases and was thus crucial for perinatal management.

Polyhydramnios is a frequent accompanying finding in fetuses with large chest masses. This is likely due to esophageal compression caused by the large thoracic mass, decreasing the fetal ability to swallow amniotic fluid.[58] The most important prognostic indicator in fetuses with CCAM is the development of hydrops. Hydrops is secondary to obstruction of the vena cava or cardiac compression from extreme mediastinal shift.[59] Historically, the development of hydrops has indicated a grave prognosis with 100% mortality,[58] and it is important to predict which fetuses are at high risk for this complication. The volume of the CCAM compared to the head circumference (CCAM volume ratio [CVR]) is an important prognostic indicator: fetuses with a CVR greater than 1.6 are more likely to develop hydrops.[60] It is also important to recognize that there is an expected period of lesion growth during the second trimester, after which the mass usually gets smaller with respect to the fetus. Therefore, CVR should be measured at multiple consecutive visits. Fetuses with extralobar BPS can also develop pleural effusions.

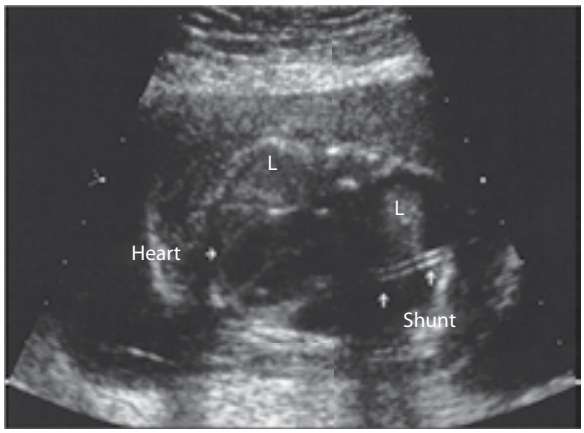

Figure 5.3 Ultrasound image of large CCAM following the placement of a thoracoamniotic shunt. L = lung.

For fetuses with large macrocystic CCAMs with a dominant cyst, or large pleural effusion causing pulmonary hypoplasia, thoracoamniotic shunting may be lifesaving: In our series of 19 high-risk fetuses who underwent prenatal shunt placement,[61] survival was 67% (6/9) in the pleural effusion group and 70% (7/10) for the CCAM group, with an average age of delivery at 33+ weeks. However, we have reported an increased risk of chest wall anomalies if shunts are placed prior to 20 weeks gestation.[62]

Fetuses with large microcystic CCAMs (thus not amenable for shunting) and signs of hydrops are more problematic. After 32 weeks gestation, delivery with immediate resection is the optimum management. In fact, given the high risk of perinatal circulatory collapse secondary to mediastinal shift and inability to ventilate, we currently perform an EXIT procedure with resection of the mass on placental support.[30] EXIT to ECMO strategy for severe masses has also been described.[63] For those fetuses <32 weeks with hydrops, open fetal surgery with thoracotomy and resection of the mass may be offered at select centers. At CHOP, we have performed 27 cases of in utero resection of fetal lung lesions for hydrops between 21 and 31 weeks gestation.[52] There were 18 healthy survivors, all of whom at resolution of hydrops at 1–2 weeks after the operation. Nine fetuses had in utero demise, with six intraoperative deaths. Intraoperative hemodynamic compromise secondary to acute changes in cardiac output upon delivery of the mass has led us to adopt a method of continuous intraoperative cardiac monitoring, with volume resuscitation of the fetus and administration of atropine prior to thoracotomy.[64] Grethel et al.[65] have reported a similar experience at University of California, San Francisco (UCSF), in which open resection of the mass in fetuses with hydrops led to the survival of 15 of 30 fetuses. While minimally invasive methods such as intrathoracic YAG laser therapy have been described,[66] technical limitations leading to damage to adjacent normal lung and ribs should prohibit offering such treatments until proven in animal models.

The recognition that maternal administration of steroids can reverse hydrops has been an exciting new development in the antenatal management of CCAM, with survival of all three hydropic fetuses in the initial report.[67] The experience at CHOP has also been favorable[68]: 11 fetuses (10 microcystic, 1 macrocystic) were given maternal betamethasone, with survival of all 5 hydropic fetuses and all 7 fetuses with CVR > 1.6 (compared to a mortality of 100% and 56%,

respectively, in historical controls). Only one patient still needed fetal intervention, while one needed resection on EXIT due to the large size of the mass; the remaining nine fetuses underwent vaginal delivery with postnatal resection without complication. The salutary effects of steroids cannot simply be ascribed to reductions in the size or rate of growth of the CCAM as there was variable growth in these patients and a natural growth plateau is well described.[56,69–71] Further studies into the basic biology of CCAM to understand how steroids may influence alveolar maturation or hydrops are areas of active research interests in several laboratories. Our current algorithm for the management of hydropic fetuses with microcystic CCAM prior to 32 weeks is to administer steroids with close observation and open lobectomy if hydrops fails to resolve.

Congenital diaphragmatic hernia

Herniation of abdominal viscera into the chest in utero occurs most commonly due to failure of the pleuroperitoneal folds to fuse normally. The left side is affected five times more commonly than the right. The ultrasonographic diagnostic criteria include herniated abdominal viscera, abnormal upper abdominal anatomy, mediastinal shift away from the side of herniation, and, in severe cases, polyhydramnios. The extent of pulmonary hypoplasia is proportional to the timing of herniation, the size of the diaphragmatic defect, and the amount of viscera herniated. Despite earlier impressions that CDH was infrequently associated with other serious congenital lung lesions, recent reports state that other major anomalies occur in 10%–50% of cases, including a high proportion of chromosomal abnormalities and cardiac anomalies.

The presence of abdominal contents intrathoracically on a transverse sonographic scan at the level of a four-chamber view of the heart is required for diagnosis. In the case of a right-sided defect, the presence of liver and especially gallbladder in the chest makes the diagnosis more clear-cut. MRI is superior in defining the position of the liver in CDH (above or below the diaphragm), which carries important prognostic significance (Figure 5.4).[72,73] Since the extent of pulmonary hypoplasia is an important prognostic indicator, MRI has the potential to become a very useful tool for more accurate measurement of hypoplastic and contralateral lung volumes as well as the extent of liver herniation.[74–76]

The best predictor of outcome in left CDH has been the right lung to head circumference ratio (LHR), defined as right lung area (measured at the level of the transverse four-chamber cardiac view) divided by head circumference (Figure 5.5).[77] The utility of LHR in predicting survival has been validated prospectively[78] and in a multicenter trial.[79] The position of the liver is an independent prognostic indicator. For example, in our experience, fetuses who have an intrathoracic liver ("liver up") need ECMO more frequently than those with the liver down (80% vs. 25%) and have a higher mortality (45% vs. 93%).[80] Given the age-related changes in normal lung area compared to head circumference through gestation, another commonly used approach is to normalize the LHR to the expected mean LHR for that gestational age, thus obtaining an "observed to expected" (O:E) ratio. CDH fetuses with an LHR O:E <25% have survival of 15%, whereas those with an LHR O:E of >45% have an excellent survival.[81] Right-sided CDH has a higher rate of prenatal complications such as polyhydramnios, premature rupture of membranes, and preterm labor.[82]

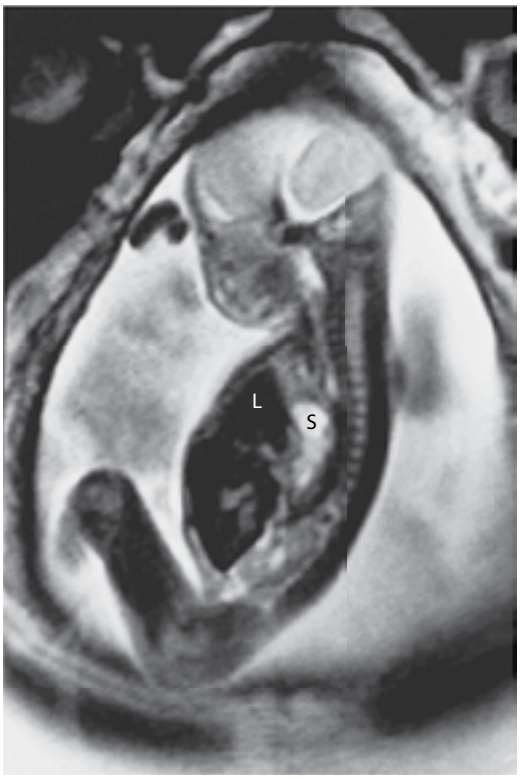

Figure 5.4 MRI of a CDH showing liver (L) and stomach (S) in the chest.

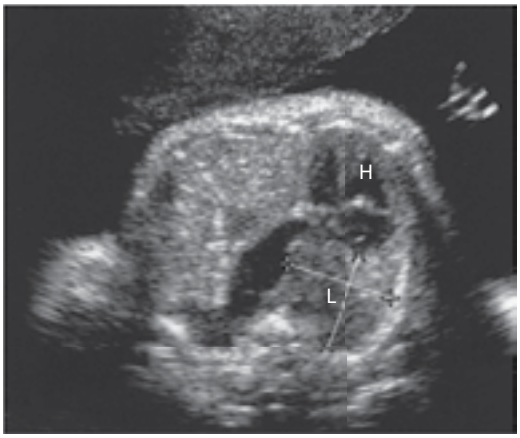

Figure 5.5 Ultrasound of CDH at the level of the transverse four-chamber view of the heart (H) showing measurements used for LHR calculation on the right lung (L).

The realization that infants with severe CDH succumb to pulmonary hypertension (more so than pulmonary hypoplasia) has fueled interest in measuring prenatal surrogates of this parameter to guide counseling and management. Fetal echocardiography may be used to measure pulmonary artery diameter,[83,84] peak early diastolic reversed flow velocity,[85] as well as pulmonary artery reactivity to maternal hyperoxygenation.[86]

The strategy for in utero treatment of CDH has undergone many permutations in the last two decades, with the current approach involving tracheal occlusion using a percutaneous, fetoscopically placed balloon (FETO) and subsequent reversal of occlusion prior to delivery (reviewed in Refs. 87 and 88). The basis for this approach is the recognition that fetal tracheal occlusion leads to compensatory lung growth due to decrease in lung liquid egress, as confirmed in lamb models of CDH.[89] Given the embryology of lung growth, occlusion earlier in gestation, prior to the pseudoglandular stage of lung development, may lead to more reliable lung growth. The outcome in fetuses after tracheal occlusion has been favorable in both the lamb model[90] and in initial clinical reports.[91,92] Although a subsequent randomized clinical trial comparing prenatal tracheal occlusion (using a clip or balloon, but without reversal) did not show a treatment benefit,[93] this may have been secondary to a generous inclusion criterion (LHR < 1.4) as well as preterm labor—still the Achilles' heel of fetal surgery. Furthermore, reversal of occlusion may confer more benefit. The European experience with fetal occlusion and reversal has been quite favorable. Jani et al.[94] reported on 24 fetuses (LHR <1, liver up) that underwent FETO between 26 and 28 weeks, with 12 undergoing reversal at 34 weeks and 12 undergoing delivery via EXIT. Survival to discharge was 50% overall (83% in the in utero reversal group; 33% in the EXIT group) compared to 9% in historical controls with the same disease severity. The mean gestational age at delivery was 33.5 weeks, although preterm premature rupture of membranes (PPROM) was still seen in 17% of patients at 28 weeks and 33% at 32 weeks. A prospective randomized trial (the TOTAL trial) is in process in Europe.

GASTROINTESTINAL LESIONS

Esophageal and bowel atresias

Esophageal atresia is typically diagnosed on prenatal ultrasound by the presence of a small or absent stomach bubble and polyhydramnios, but no ultrasound finding is sensitive or specific for esophageal atresia.[95] Esophageal atresia is associated with anatomic and chromosomal abnormalities in 63% of cases,[96] most notably trisomy 18 and VACTERL (vertebral anomalies, anal atresia, cardiac anomalies, tracheoesophageal fistula, renal agenesis, and limb defects).

Duodenal atresia has a characteristic "double bubble" appearance on prenatal ultrasound, resulting from dilatation of the stomach and proximal duodenum. The incidence of associated malformations is high (57% in one recent series[97]—classically with Down's syndrome and endocardial cushion defects), and those who are prenatally diagnosed are more likely to have associated anomalies.[97] In a recent review of all small intestinal atresias, Hemming and Rankin[98] reported that 25% have chromosomal anomalies and 25% have other structural anomalies.

There are many bowel abnormalities that may be noted on prenatal ultrasound (dilated bowel, ascites, cystic masses, hyperperistalsis, polyhydramnios); however, none is absolutely predictive of postnatal outcome. Patients with obstruction frequently have findings of increased bowel diameter (especially in the third trimester), hyperperistalsis, or polyhydramnios, but ultrasound is much less sensitive in diagnosing large bowel anomalies than those in small bowel.[99] Since the large bowel is mostly a reservoir, with no physiologic function in utero, defects in this region such as anal atresia or Hirschsprung's disease are difficult to detect, although low MSAFP may be a marker for anal atresia.[100] Small bowel obstruction may be associated with cystic fibrosis; therefore, all such fetuses should undergo perinatal evaluation for this disease.[99]

ABDOMINAL WALL DEFECTS

Omphalocele is thought to be secondary to failure of the abdominal viscera to return to the abdomen in the 10th week of gestation.[101] It characteristically has a viable sac composed of amnion and peritoneum containing herniated abdominal contents. The defect is in the midline, usually near the insertion point of the umbilical cord. Ultrasound may demonstrate the internal viscera and sometimes the liver within the sac. Ascites may also be present. Since chromosomal and structural abnormalities are very common in omphalocele (cardiac and renal anomalies, chromosomal anomalies including Beckwith–Wiedemann syndromes and Pentalogy of Cantrell), fetuses with this defect should be screened by karyotype in addition to a detailed sonographic review and echocardiogram.[102] Omphalocele is rarely seen as part of the OEIS sequence (omphalocele, exstrophy of the bladder, imperforate anus, and spinal anomalies),[103] requiring multiple operations with considerable morbidity. Patients with giant omphaloceles (containing predominantly liver, with a defect >5 cm) can have a prolonged course with high long-term morbidity, especially with respiratory and feeding difficulties.[104]

Gastroschisis is more often an isolated lesion with a right para-umbilical defect.[102] There is no membrane covering the exposed bowel. On ultrasound, the bowel appears free-floating, and the loops may appear thickened due to peel formation from exposure to amniotic fluid (Figure 5.6). Dilated loops of bowel may be seen from obstruction secondary to protrusion from a small defect or from the presence of an atresia, seen in 8–10% in most series. The pathophysiology of bowel damage is likely due to amniotic fluid exposure and bowel constriction, the latter leading to ischemia and venous obstruction.[105,106] There is a rate of third trimester fetal demise in about

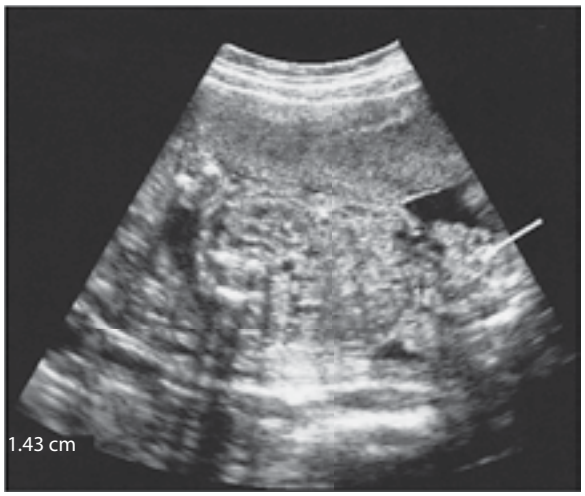

Figure 5.6 Ultrasound of a fetus with gastroschisis with crossmarks showing the abdominal wall defect and arrow indicating extra-abdominal bowel.

5%,[107] highlighting the need for careful, serial monitoring once the diagnosis is made. Many infants have intrauterine growth retardation: 70% are below the 50th percentile at birth (this number may be overestimated on prenatal measurements, since the abdominal cavity is small because of the defect).[102]

Predicting outcome in fetuses with gastroschisis based on prenatal ultrasound findings remains a challenge. Analysis of infants with gastroschisis has led to the definition of two groups of patients: simple (isolated gastroschisis, very low mortality) vs. complex (those who also have bowel atresias, perforation, volvulus, or bowel necrosis and a higher mortality [28% in Ref. 108; 8.7% in Ref. 109]). It is therefore crucial to develop prenatal diagnostic criteria for prediction of postnatal outcome. In addition, the timing of delivery has been an unanswered question: the urgency to prevent in utero bowel damage must be tempered with the risks of prematurity in these infants, many of whom are small for gestational age. Both ultrasound and biochemical characteristics have been examined to address this issue. Examination of amniotic fluid for markers of fetal distress such as meconium[110] and β-endorphin[111] may carry prognostic significance but is not currently used in clinical practice. Ultrasound characteristics such as bowel dilatation, bowel wall thickening, and mesenteric flow have been studied by many groups as possible prognostic indicators. We recently reviewed our experience with 64 cases of gastroschisis seen at CHOP between 2000 and 2007[112]; 53 were simple and 11 were complex (17%). There were three in utero mortalities (two fetal demises and one termination) with an overall perinatal mortality of 9%. Interestingly, prenatal ultrasound findings were not predictive of the postnatal course for any of the parameters examined (simple vs. complex, primary vs. silo, hospital length, time to enteral feedings, etc.).

The question of whether Caesarian section delivery would protect the exposed bowel from further damage during delivery has been considered but does not appear to confer any outcome benefit.[113,114] Thus, the mode of delivery for abdominal wall defects can be vaginal except in cases of giant omphalocele, in whom the risk of liver rupture and dystocia mandates a Caesarian section. The issue of whether transport prior to delivery impacts outcome (secondary to ongoing ischemia and damage to the exposed intestines during transport) has also been studied and, interestingly, did not appear to make a difference in one series.[115] Our current strategy for management is serial ultrasounds to monitor for signs of fetal distress, with planned delivery at term and either primary or silo closure.

PRENATAL DIAGNOSIS OF RENAL ANOMALIES

Prenatally diagnosed HN represents a broad spectrum of diseases with widely disparate prognoses (reviewed in Ref. 116). The ultrasound findings of HN include dilated renal pelvis and calyces, with or without dilatation of the bladder and ureter, depending on the cause of HN (Figure 5.7). The Society for Fetal Urology defines four grades with increasing severity, with grade 1 being split pelvis only and grade 4 being dilated pelvis with distended calyces and thinned parenchyma.[117] In addition, an anterior–posterior diameter >10 mm has been suggested as being predictive of fetuses who will need some postnatal intervention.[118] The differential diagnosis of prenatal HN includes ureteropelvic junction (UPJ) obstruction, multicystic kidney, primary obstructive megaureter, ureterocele, ectopic ureter, and posterior urethral valves (PUV).[119] Severe, bilateral HN leads to oligohydramnios with a fetus small for gestational age. Because of the lack of amniotic fluid, ultrasound diagnosis may be difficult and MRI may help define the cause of HN.[5]

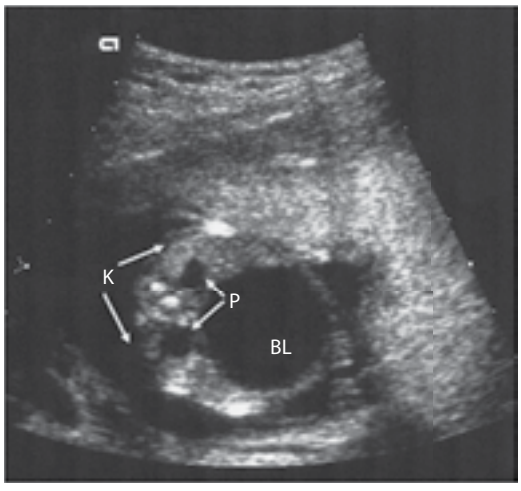

Figure 5.7 Ultrasound of HN showing enlarged bladder (BL), compressed renal parenchyma (K), and dilated renal pelvises (P).

UPPER URINARY TRACT OBSTRUCTION

The most common cause of prenatal HN is UPJ obstruction. The prognosis of prenatally diagnosed HN is excellent, if there is unilateral disease[120] and if the renal pelvic diameter is less than 10 mm.[121] In one large series, 80% were normal at 3 years and 17% were normal at birth, suggesting spontaneous resolution of the problem.[122] Only 17% needed surgical intervention. Prenatally diagnosed HN requires follow-up with ultrasound at birth and at 1 month. If there is any evidence of abnormality, a voiding cystourethrogram and diuretic renal scintigram should be performed.[123]

LOWER URINARY TRACT OBSTRUCTION

The most common cause of lower urinary tract obstruction (LUTO) is PUV; it is also seen in prune belly syndrome and urethral atresia.[124] The most important factor in the morbidity and mortality from fetal urethral obstruction is pulmonary hypoplasia secondary to oligohydramnios.[125] For patients with PUV, prenatal diagnosis defines a subgroup of patients with very poor prognosis, with 64% incidence of renal failure and transient pulmonary failure, compared to 33% in the postnatally diagnosed group.[126] Serial fetal urine analysis may provide prognostic information in this group of fetuses. Drainage of the bladder three times at 48–72 hour intervals with measurement of sodium, chloride, osmolality, calcium, β-2 microglobulin, and total protein should be performed to determine renal function. In this strategy, the later taps indicate the characteristics of recently produced urine, and a decrease in the electrolytes, proteins, and tonicity correlates with a favorable outcome.[124]

The rationale for prenatal intervention originates from sheep models of the disease, in which bladder outlet obstruction in fetal lambs reproduced the pulmonary hypoplasia and renal dysplasia seen in patients with bilateral obstructive uropathy.[127] Correction of the obstruction led to normal lung growth.[128] Fetal intervention in prenatal obstructive uropathy is only warranted in male fetuses with oligohydramnios, bladder distention, and bilateral HN (with no other abnormalities), who have improving urine profiles with serial bladder drainage.[129] In female fetuses, LUTO is generally part of a complex cloacal anomaly, and fetal intervention has not been beneficial. Male fetuses may be considered for vesicoamniotic (V-A) shunting,[130] and fetal microcystoscopy and mechanical valve disruption have been reported.[131]

Although V-A shunting in a fetus with oligohydramnios can be technically challenging, the survival benefit of prenatal shunting in carefully selected populations of fetuses has been reported, with 43% of patients having normal renal function 2 years after birth.[132] We reported our series of 18 patients who had V-A shunts for PUV (7), prune belly syndrome (7), and urethral atresia (4).[133] Eight patients have good renal function, four have mild renal insufficiency, and six required hemodialysis with subsequent transplantation. Respiratory problems and frequent urinary tract infections were seen in eight and nine patients, respectively. While short-term outcomes are variable in different reports,[120] a recent meta-analysis[134] determined that in utero drainage improved survival compared to postnatal management alone in the group of fetuses with poor prognosis. Patients who have been shunted can still die from pulmonary hypoplasia as well as renal failure. A prospective randomized trial (PLUTO) in Europe showed difficulties in patient recruitment, a higher survival with V-A shunting, but less than optimal renal function in some survivors.[135]

MYELOMENINGOCELE

Myelomeningocele (MMC) is a neural tube defect characterized by the protrusion of the spinal cord and meninges through open vertebral arches. It is the most common form of spina bifida, which affects 1 in 2000 births per year. Maternal serum testing identifies 75%–80% of pregnancies with MMC by 16 weeks of age.[136] If an increase in serum AFP is noted, amniocentesis is performed to assess amniotic fluid AFP and acetylcholinesterase to confirm the diagnosis.[137] The ultrasound characteristics include the "lemon" and "banana" signs, which are scalloping of the frontal bone and abnormal anterior curvature of the cerebellar hemispheres, respectively.[138] Most fetuses have an associated Arnold–Chiari malformation, characterized on fetal MRI by the caudal displacement of the vermis and cerebellum with midbrain herniation through the foramen magnum. Ultrasound confirmation can be made as early as 18 weeks, which allows localization of the defect as well as assessment of limb function, and the presence of clubbing or of the Arnold–Chiari malformation (Figure 5.8).

Analysis of the potential benefits of fetal repair of MMC has been accomplished in sheep models of the defect,[139–141] thus providing a compelling reason for in utero repair, the first nonlethal disease to be considered for this treatment. The goals of fetal repair are to prevent the chemical and mechanical trauma to the exposed spinal cord, to resolve

Figure 5.8 Ultrasound of a fetus with MMC showing the sac (crossmarks) over the spinal defect (arrow).

Figure 5.9 MRI of a fetus with MMC showing hindbrain herniation (arrow).

the hindbrain herniation frequently seen with this defect, to decrease the need for postnatal ventriculoperitoneal shunt, and to allow time for possible neural regeneration after repair. We reported the first open repair of fetal MMC, which led to improved neurological outcome[142] and resolution of the Arnold–Chiari malformation (Figure 5.9). Long-term analysis of patients who underwent in utero repair has indicated that this may lead to a decreased need for ventriculoperitoneal shunting[143,144] as well as improved brainstem function[145] and neurodevelopmental outcomes.[146] The multicenter Management of Myelomeningocele Study (MOMS trial) demonstrated benefits of prenatal repair such as a decreased rate of ventricular shunting and improved motor function including the ability to walk.[147]

CONCLUSIONS

Prenatal ultrasound has led to a rapid increase in the number of pediatric surgical conditions diagnosed in utero. Prenatal detection and serial sonographic study of fetuses with anatomic lesions now make it possible to define the natural history of these abnormalities, determine the pathophysiologic causes that affect outcome, and formulate management based on prognosis. Since many congenital anomalies are associated with others, it is important to perform a careful ultrasound evaluation and karyotype analysis when one abnormality is discovered.

Careful evaluation of patients followed prenatally and postnatally, as well as studies of congenital defects in animal models, has defined select populations of fetuses who may benefit from prenatal intervention. In most cases, these are fetuses who would not be expected to survive the prenatal period given the natural history of their disease. Further progress in prenatal diagnosis and monitoring as well as continued reevaluation of outcomes will undoubtedly tune our current algorithms regarding the management of these congenital anomalies. Pediatric surgeons have a unique opportunity to continue to shape this exciting field in the new millennium.

Fetal counseling for surgical malformations

KOKILA LAKHOO

INTRODUCTION

Pediatric surgeons are often called to counsel parents once a surgical abnormality is diagnosed on a prenatal scan. The referral base for a pediatric surgeon now includes the perinatal period. Expertise in surgical correction of congenital malformations may favorably influence the perinatal management of prenatally diagnosed anomalies by changing the site of delivery for immediate postnatal treatment; altering the mode of delivery to prevent obstructed labor or hemorrhage: early delivery to prevent ongoing fetal organ damage; or treatment in utero to prevent, minimize, or reverse fetal organ injury as a result of a structural defect. Recent literature has confirmed the favorable impact of prenatal surgical consultation in influencing the site of delivery in 37% of cases, changing the mode of delivery in 6.8%, reversing the decision to terminate a pregnancy in 3.6%, and influencing the early delivery of babies in 4.5%.

The pediatric surgeon performing prenatal consultations must be aware of differences between the prenatal and postnatal natural history of the anomaly. There is often a lack of understanding of the natural history and prognosis of a condition presenting in the newborn and the same condition diagnosed prenatally.

The diagnosis and management of complex fetal anomalies require a multidisciplinary team encompassing obstetricians, neonatologists, geneticists, pediatricians, pediatric surgeons, and occasional other specialists with expertise to deal with all the maternal and fetal complexities of a diagnosis of a structural defect. This team should be able to provide information to prospective parents on fetal outcomes, possible interventions, appropriate setting, time and route of delivery, and expected postnatal outcomes. The role of the surgical consultant in this team is to present information regarding the prenatal and postnatal natural history of an anomaly, its surgical management, and the long-term outcome.

CONGENITAL MALFORMATION

Congenital malformations account for one of the major causes of perinatal mortality and morbidity. Single major birth defects affect 3% of newborns, and 0.7% of babies have multiple defects. The prenatal hidden mortality is higher since the majority abort spontaneously. Despite improvements in perinatal care, serious birth defects still account for 20% of all deaths in the newborn period and an even greater percentage of serious morbidity later in infancy and childhood. The major causes of congenital malformation are chromosomal abnormalities, mutant genes, multifactorial disorders, and teratogenic agents.

PRENATAL DIAGNOSIS

Prenatal diagnosis has remarkably improved our understanding of surgically correctable congenital malformations. It has allowed us to influence the delivery of the baby, offer prenatal surgical management, and discuss the options of termination of pregnancy for seriously handicapping or lethal conditions. Antenatal diagnosis has also defined an in utero mortality for some lesions such as diaphragmatic hernia and sacrococcygeal teratoma (SCT) so that true outcomes can be measured. Prenatal ultrasound (US) scanning has improved since its first use 30 years ago, thus providing better screening programs and more accurate assessment of fetal anomaly. Screening for Down syndrome may now be offered in the first trimester (e.g., nuchal scan combined test) (Figure 6.1) or second trimester (e.g., quadruple blood test). Better resolution and increased experience with US scans has led to the recognition of US soft markers, which have increased the detection rate of fetal anomalies but at the expense of higher false-positive rates.

Routine US screening identifies anomalies and places these pregnancies in the high-risk categories with maternal diabetes, hypertension, genetic disorders, raised alpha-fetoprotein (AFP), etc. High-risk pregnancies may be offered further invasive diagnostic investigations such as amniocentesis or chorionic villous sampling (CVS). Structural abnormalities difficult to define on US such as hindbrain lesions or the presence of oligohydramnios are better imaged on ultrafast magnetic resonance imaging (MRI). With the increasing range of options and sophistication of diagnostic methods,

parents today are faced with more information, choice, and decisions than ever before, which can create as well as help to solve dilemmas. The different tests and screening procedures commonly in use are outlined here.

US examination

US scans are routinely performed at 18–20 weeks gestation as part of the prenatal screening for all pregnancies in England and Wales. Older mothers are routinely screened but in addition are offered invasive testing. Pregnancies with maternal risk factors such as raised AFP levels, genetic disorders, and family history of chromosomal abnormalities or monochorionic twins that carry a high risk for chromosomal anomalies are offered earlier scans in the first trimester. Abnormalities such as diaphragmatic hernia may be detected as early as 11 weeks gestation. First-trimester scans are also useful for accurately dating pregnancies and defining chorionicity in multiple pregnancies.

Recently, nuchal translucency (NT) measurements have emerged as an independent marker of chromosomal abnormalities (with a sensitivity of 60%), structural anomalies (particularly cardiac defects), and some rare genetic syndromes. It involves measuring the area at the back of the fetal neck at 11–14 weeks gestation (Figure 6.1). The mechanisms by which some abnormalities give rise to this transient anatomical change of NT are poorly understood. Although some abnormalities can be seen at the time of the nuchal scan (11–14 weeks), most are detected at the 18th- to 20th-week anomaly scan. Some abnormalities such as gastroschisis have a higher detection rate on a scan than others, e.g., cardiac abnormalities.

If the NT measurement is increased and the karyotype is normal, there is a higher risk for a cardiac anomaly, and these high-risk fetuses may be referred for fetal echocardiography, which provides better prenatal cardiac assessment than the routine screening scan. US surveillance is essential during the performance of invasive techniques such as amniocentesis, CVS, and shunting procedures. It is also useful for assessing fetal viability before and after such procedures. Some abnormalities such as tracheoesophageal fistula (TOF), bowel atresia, diaphragmatic hernia, and hydrocephaly may present later in pregnancy and are thereby not detected on the routine 18th-week scan.

Overall, around 60% of structural birth defects are detected prenatally, but the detection rate varies from 0% (isolated cleft palate) to close to 100% (gastroschisis) depending on the defect. True wrong diagnoses are rare, but false-positive diagnoses do occur; some are due to natural prenatal regression, but most are due to US soft markers.

US soft markers are changes noted on prenatal scan that are difficult to define. Examples are echogenic bowel,[1] hydronephrosis, and nuchal thickening. Their presence creates anxiety amongst sonographers since the finding may be transient with no pathological relevance or may be an indicator of significant anomalies such as chromosomal abnormalities, cystic fibrosis (echogenic bowel), Down syndrome (nuchal thickening), or renal abnormalities (hydronephrosis). Once soft markers are detected, whether they should be reported or further invasive tests offered is a dilemma faced by obstetricians. Reporting these markers has increased detection rates at the expense of high false-positive rates.

US is routinely performed as a prenatal screening test. The reliability of the information obtained is dependent on the expertise and experience of the person performing the scan. In a recent study, congenital anomalies noted at birth were diagnosed on prenatal scan in 64% of cases, with 0.5% opting for termination.

Figure 6.1 Nuchal thickening.

Minimally invasive techniques

CELL-FREE FETAL DNA

The identification of cell-free fetal DNA (cffDNA) in the maternal circulation triggered an increase in research with the aim of developing safer, minimally invasive prenatal diagnosis. It is placental based and detectable from 4 weeks gestation and is rapidly cleared after delivery. The majority of cffDNA is maternal, with only 3%–6% originating from the fetus. Difficulties with separating these means that applications have focused on detection of genetic material that should not be present in the mother, such as Y chromosome sequences. Fetal Rh-D typing using cffDNA has now almost completely replaced invasive testing for determination of fetal blood group in the United Kingdom.

PREIMPLANTATION GENETIC DIAGNOSIS

For couples known to be carrying a genetic disorder, the process of invasive prenatal diagnosis and potential termination of pregnancy can be distressing. Preimplantation genetic diagnosis (PGD) involves generation of embryos by in vitro fertilization (IVF) and then sampling at the eight-cell stage. The genetic analysis is carried out the same day and only unaffected embryos are transferred into the uterus.

PGD is extremely promising for families affected by genetic disorders but has also given rise to many legal and ethical challenges such as its use to produce an unaffected, human leukocyte antigen (HLA)-compatible "savior sibling."

Invasive diagnostic tests

Amniocentesis and CVS are the two most commonly performed invasive diagnostic tests.

AMNIOCENTESIS

Amniocentesis is commonly used for detecting chromosomal abnormalities and less often for molecular studies, metabolic studies, and fetal infection. It is performed after 15 weeks gestation and carries a low risk of fetal injury or loss (0.5%–1%). Full karyotype analysis takes approximately 2 weeks, but newer rapid techniques using fluorescent in situ hybridization (FISH) or polymerase chain reaction (PCR) can give limited (usually for trisomies 21, 18, and 13) results within 2–3 days.

CHORIONIC VILLOUS SAMPLING

CVS is the most reliable method for first-trimester diagnosis and may be performed at 10–14 weeks gestation. The test involves US-guided biopsy of the chorionic villi. The added risk of fetal loss is approximately 1%–2%. The samples obtained may be subjected to a variety of tests including full karyotype, rapid karyotyping (FISH–PCR), enzyme analysis, or molecular studies. Approximate timing of chromosomal results is 1–2 weeks for karyotyping and 2–3 days for FISH and PCR.

PRENATAL MATERNAL SERUM SCREENING

Interest in detecting circulating fetal cells in maternal blood for diagnostic purposes has grown since the advent of fluorescence-activated cell sorting (FACS). The observation of high levels of AFP in amniotic fluid of pregnancies complicated by open neural tube defects (NTDs) popularized this test.[1] However, with increasing accuracy of US diagnosis, maternal serum screening of AFP solely for identification of NTDs cannot be justified. The more popular maternal serum screening test is the triple test (human chorionic gonadotrophin [HCG], AFP, estrogen) used in combination with the nuchal scan.

FETAL BLOOD SAMPLING

Rapid karyotyping of CVS and FISH and PCR of amniotic fluid samples have replaced fetal blood sampling (FBS) for many conditions. However, FBS is still required for the diagnosis and treatment of hematological conditions and some viral infections. When required, it is best performed by US-guided needle sampling after 18 weeks gestation rather than the more invasive fetoscopic technique. Mortality from this procedure is reported to be 1%–2%.

FETAL SURGERY

Fetal intervention encompasses a range of procedures on the fetus with congenital structural anomalies, while still on the placental circulation. There is a spectrum of interventions ranging from simple aspiration of cysts to open fetal surgery. The concept of fetal surgery was conceived in order to prevent fetal or early postnatal death, or to prevent permanent irreversible organ damage. The benefit of these procedures has to be balanced with risks to both the mother and the fetus. Open fetal surgery, more commonly conducted in North American centers, involves open surgery to the uterus in order to operate on the fetus. Fetal intervention centers in Europe more commonly use minimally invasive fetoscopic surgery. Minimally invasive techniques such as ablation of vessels in SCT, fetoscopic ablation of posterior urethral valves (PUVs), tracheal occlusion for congenital diaphragmatic hernia (CDH), etc. are currently under trial. However, laser ablation in twin-to-twin transfusion is now well established.

GENETIC DIAGNOSES

Antenatal detection of genetic abnormalities is increasing especially in high-risk pregnancies. Previously undiagnosed conditions such as cystic fibrosis, Beckwith–Wiedemann syndrome, Hirschsprung disease, sickle cell disease, etc. may be detected prenatally following invasive testing and genetic counseling and assessment offered early in pregnancy.

Future developments

The aim of prenatal diagnosis and testing is to have 100% accuracy without fetal loss or injury and no maternal risk. National plans to improve Down screening using US and biochemical combination tests are now in place in the United Kingdom. Research into new markers for chromosomal abnormalities is ongoing. The fetal nasal bone is one such example, which may assist in detecting babies with chromosomal abnormalities.

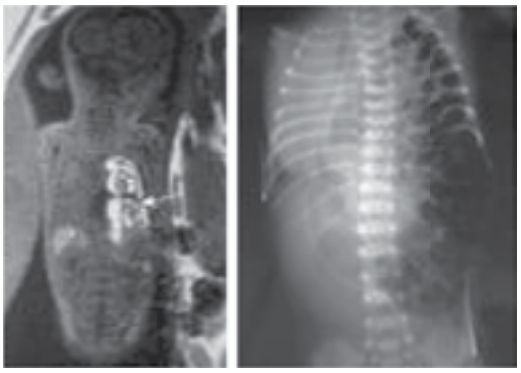
Management of Rhesus disease is showing promise whereby fetal blood groups may be determined from maternal blood samples through detection of free fetal DNA. The search for fetal components in maternal blood is an exciting and expanding field of research since past and present efforts to isolate and use them for diagnosis have met with little success. Rapid detection techniques versus traditional cultures for karyotyping are currently under debate at present.

Three-dimensional images from new US machines may have a useful role in diagnosis and assessment of facial deformities such as cleft lip and palate. MRI may assist in better defining some lesions difficult to view on conventional prenatal scanning, such as presacral teratoma, PUVs in the presence of oligohydramnios, and hindbrain lesions.

SPECIFIC SURGICAL CONDITIONS

Congenital diaphragmatic hernia

CDH accounts for 1 in 3000 live births and challenges the neonatologist and pediatric surgeons in the management of this high-risk condition (Figure 6.2). Mortality remains high (more than 60%) when the hidden mortality of in utero



(a) (b)

Figure 6.2 Congenital left diaphragmatic hernia shown on **(a)** prenatal MRI and **(b)** postnatal radiograph.

death and termination of pregnancy are taken into account. Lung hypoplasia and pulmonary hypertension account for most deaths in isolated CDH newborns. Associated anomalies (30%–40%) signify a grave prognosis with a survival rate of less than 10%.

In the United Kingdom, most CDHs are diagnosed at the 20th-week anomaly scan with a detection rate approaching 60%, although as early as 11 weeks gestation has been reported. MRI has a useful role in accurately differentiating CDH from cystic lung lesions and may be useful in measuring fetal lung volumes as a predictor of outcome. Cardiac anomalies (20%), chromosomal anomalies of trisomy 13 and 18 (20%), and urinary, gastrointestinal, and neurological anomalies (33%) can coexist with CDH and should be ruled out by offering the patient a fetal echocardiogram, amniocentesis, and detailed anomaly scan. For these associated anomalies and in isolated lesions, early detection, liver in the chest, polyhydramnios, and fetal lung-to-head ratio (LHR) of less than 1 are implicated as poor predictors of outcome.

Greater consistency and accuracy in predictive value can be obtained by using the observed-to-expected LHR (O/E LHR). The O/E LHR was developed in response to the observation that lung growth is four times that of head growth in the third trimester. The O/E LHR (by taking a transverse section of the fetal chest demonstrating the four-chamber view of the heart and multiplying the contralateral lung area's longest diameter by the longest perpendicular to it) is said to eliminate miscalculation. The O/E LHR is lower in fetuses with CDH compared to normal fetuses, and lower still in babies who die with CDH than those who survive.

In these patients with poor prognostic signs, fetal surgery for CDH over the last two decades has been disappointing; however, benefit from fetal intervention with tracheal occlusion (FETO) awaits randomized studies. One ongoing trial in Europe aims to enroll patients with severe hypoplasia (O/E LHR <25%) and randomize half to FETO. The acronym for the trial is TOTAL (Tracheal Occlusion to Accelerate Lung Growth, www.totaltrial.eu).

Favorable outcomes in CDH with the use of antenatal steroids has not been resolved in the clinical setting. Elective delivery at a specialized center is recommended with no benefit from caesarean section.

Postnatal management is aimed at reducing barotrauma to the hypoplastic lung by introducing high-frequency oscillatory ventilation (HFOV) or permissive hypercapnea, and treating the severe pulmonary hypertension with nitric oxide. No clear benefits for CDH with extracorporeal membrane oxygenation (ECMO) have been concluded in a 2002 Cochrane ECMO study.

Surgery for CDH is no longer an emergency procedure. Delayed repair following stabilization is employed in most pediatric surgical centers. Primary repair using the transabdominal route is achieved in 60%–70% of patients, with the rest requiring a prosthetic patch. Complications of sepsis or reherniation with prosthetic patch requiring revision are recorded in 50% of survivors.

Cystic lung lesions

Congenital cystic adenomatoid malformations (CCAMs), bronchopulmonary sequestrations (BPSs), or "hybrid" lesions containing features of both are common cystic lung lesions noted on prenatal scan (Figures 6.3 and 6.4). Less common lung anomalies include bronchogenic cysts, congenital lobar emphysema, and bronchial atresia. Congenital cystic lung lesions are rare anomalies, with an incidence of 1 in 10,000 to 1 in 35,000.

Prenatal detection rate of lung cysts at the routine 18th- to 20th-week scan is almost 100% and may be the most common mode of actual presentation. Most of these lesions are easily distinguished from CDH; however, sonographic

Figure 6.4 **(a)** Chest radiograph and **(b)** CCAM of right upper lobe.

features of CCAM or BPS are not sufficiently accurate and correlate poorly with histology. MRI, though not routinely used, may provide better definition for this condition; however, inaccuracies were reported in 11% of cases.

Bilateral disease and hydrops fetalis (5%) are indicators of poor outcome, whereas mediastinal shift, polyhydramnios, and early detection are not poor prognostic signs. In the absence of termination, the natural fetal demise of antenatally diagnosed cystic lung disease is 28%. Spontaneous involution of cystic lung lesions can occur, but complete postnatal resolution is rare, and apparent spontaneous "disappearance" of antenatally diagnosed lesions should be interpreted with care, as nearly half of these cases subsequently require surgery.

Close monitoring of the antenatally detected lesion with serial USs to detect the size of the lesion, location, volume, blood supply, and compromise to the fetus is performed. The cystic adenomatous malformation volume ratio predicts an 80% increased risk of hydrops fetalis if more than 1.6; a ratio less than 1.6 is associated with a survival rate of 94% and less than 3% risk of hydrops fetalis.

In only 10% of cases, the need for fetal intervention arises. The spectrum of intervention include simple centesis of amniotic fluid, thoracoamniotic shunt placement, percutaneous laser ablation, and open fetal surgical resection. Maternal steroid administration has also been reported to have a beneficial effect on some CCAMs, although the mechanism is unclear. A large cystic mass and hydrops in isolated cystic lung lesions are the only real indication for fetal intervention.

Normal vaginal delivery in recommended unless maternal condition indicates otherwise. Large lesions are predicted to become symptomatic shortly after birth (as high as 45% in some series); thus, delivery at a specialized center would be appropriate. However, smaller lesions are less likely to be symptomatic at birth, and delivery could be done at the referring institution with follow-up in a pediatric surgery clinic.

Postnatal management is dictated by clinical status at birth. Symptomatic lesions require urgent radiological evaluation with chest radiograph and, ideally, computed tomography (CT) scan (Figure 6.2) followed by surgical excision. In asymptomatic cases, postnatal investigation consists of chest CT scan within 1 month of birth, even if regression or resolution is noted on prenatal scanning. Plain radiography should not be relied upon since it will miss and underestimate many lesions.

Surgical excision of postnatal asymptomatic lesions remains controversial, with some centers opting for conservative management. The approach to treating this asymptomatic group has evolved in some centers, whereby a CT scan is performed within 1 month postbirth, followed by surgery before 6 months of age due to the inherent risk of infection and malignant transformation. Small lesions, less than 1 cm, may be managed expectantly, bearing in mind that the true resolution of these lesions is exceptional. Successful outcome of greater than 95% has been reported for these surgically managed asymptomatic lung lesions.

Congenital high airway obstruction syndrome (CHAOS) is usually caused by laryngeal atresia or tracheal obstruction and can be detected from about 17 weeks. Due to lack of communication, fluid is accumulated in the tracheobronchial tree. Sonographic appearance of CHAOS has distinctive features of bilaterally massively enlarged, uniformly hyperechogenic lungs, with eversion of the diaphragm and compression of the heart. It results in a picture suggestive of a small heart surrounded by massive lungs. In some, the absence of tracheal flow in color Doppler can be visualized during fetal breathing movements. CHAOS is usually isolated but may be a feature of Fraser syndrome. The antenatal history of CHAOS depends on the severity of obstruction; however, in the vast majority of cases, this condition is fatal.

Abdominal wall defects

Abdominal wall defects in fetuses include gastroschisis, exomphalos, bladder exstrophy complex, cloacal exstrophy, and body stalk syndrome. The defects that occur more commonly are gastroschisis and exomphalos, but these are distinct abdominal wall defects with an unclear etiology and a controversial prognosis. Attention may be drawn to their presence during the second trimester because of raised maternal serum APF level or abnormal US scan.

EXOMPHALOS

Exomphalos is characteristically a midline defect, at the insertion point of the umbilical cord, with a viable sac composed of amnion and peritoneum containing herniated abdominal contents (Figure 6.5). Incidence is known to be 1 in 4000 live births. Associated major abnormalities—which include trisomy 13, 18, and 21; Beckwith–Wiedemann syndrome (macroglossia, gigantism, exomphalos); pentology of Cantrell (sternal, pericardial, cardiac, abdominal wall, and diaphragmatic defect); and cardiac, gastrointestinal, and renal abnormalities—are noted in 60%–70% of cases. Thus karyotyping, in addition to detailed sonographic review and fetal echocardiogram, is essential for complete prenatal screening. Fetal intervention is unlikely in this condition. If termination is not considered, normal vaginal delivery at a center with neonatal surgical expertise is recommended and delivery by caesarean section only reserved for large exomphalos with exteriorized liver to prevent damage.

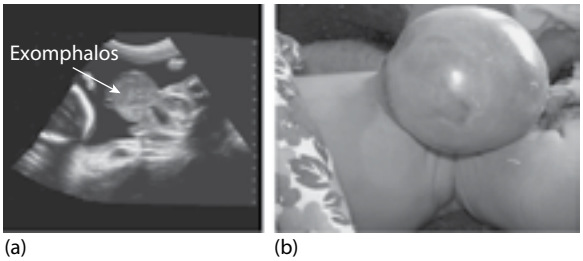

Figure 6.5 **(a)** Prenatal and **(b)** postnatal images of exomphalos.

Surgical repair includes primary closure or a staged repair with a silo for giant defects. Occasionally, in vulnerable infants with severe pulmonary hypoplasia or complex cardiac abnormalities, the exomphalos may be left intact and allowed to slowly granulate and epithelialize by application of antiseptic solution. Postnatal morbidity occurs in 5%–10% of cases. Malrotation and adhesive bowel obstruction does contribute to mortality in isolated exomphalos; however, the majority of these children survive to live normal lives.

GASTROSCHISIS

Gastroschisis is an isolated lesion that usually occurs on the right side of the umbilical defect with evisceration of the abdominal contents directly into the amniotic cavity (Figure 6.6). The incidence has increased from 1.66 per 10,000 births to 4.6 per 10,000 births, affecting mainly young mothers typically less than 20 years old. Associated anomalies are noted in only 5%–24% of cases with bowel atresia, the most common coexisting abnormality. On prenatal scan with a detection rate of 100%, the bowel appears to be free-floating, and the loops may appear to be thickened due to damage by amniotic fluid exposure causing a "peel" formation. Dilated loops of bowel (Figure 6.3) may be seen from obstruction secondary to protrusion from a defect or atresia due to intestinal ischemia.

Predicting outcome in fetuses with gastroschisis based on prenatal US findings remains a challenge. There is some evidence that US monitoring of growth, umbilical artery Doppler, and bowel diameter measurements lead to early detection of complications and can help improve mortality. However, a recent systematic review looking at the outcome of antenatal bowel dilatation showed no difference in mortality, length of bowel resection, time to feeding, or length of hospital stay. To reduce the rate of third-trimester fetal loss, serial USs are performed to monitor the development of bowel obstruction, and delivery at around 37 weeks is recommended at a center with neonatal surgical expertise.

A recent study[5] has challenged elective preterm delivery with a randomized control trial. Delivery by caesarean section has no advantage over normal vaginal route. Despite efforts to plan elective delivery, 50% of cases will require emergency caesarean section due to development of fetal distress.

Various methods of postnatal surgical repair include the traditional primary closure, reduction of bowel without anesthesia, reduction by preformed silo, or reduction by means of a traditional silo. Coexisting intestinal atresia could be repaired by primary anastomosis or staged with stoma formation. Variation in achieving full enteral feeding due to prolonged gut dysmotility is expected in all cases.

The long-term outcome in gastroschisis is dependent on the condition of the bowel. In uncomplicated cases, the outcome is excellent in more than 90%. The mortality of live-born infants is 5%, with a further 5% suffering short bowel syndrome and 10% requiring surgery for adhesive bowel obstruction. Late third-trimester fetal loss should always be mentioned during fetal counseling.

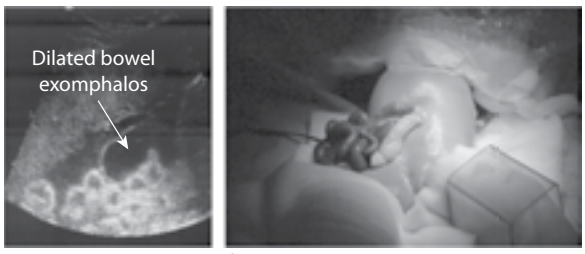

Figure 6.6 **(a)** Prenatal and **(b)** postnatal images of gastroschisis.

Tracheoesophageal fistula and esophageal atresia

Repair of TOF)/esophageal atresia (EA) is a condition that measures the skill of pediatric surgeons from trainee to independent surgeon (Figure 6.7). The incidence is estimated at 1 in 3000 births. Prenatally, the condition may be suspected from maternal polyhydramnios and absence of a fetal stomach bubble at the 20th-week anomaly scan. Prenatal scan diagnosis of TOF/OA is estimated to be less than 42%

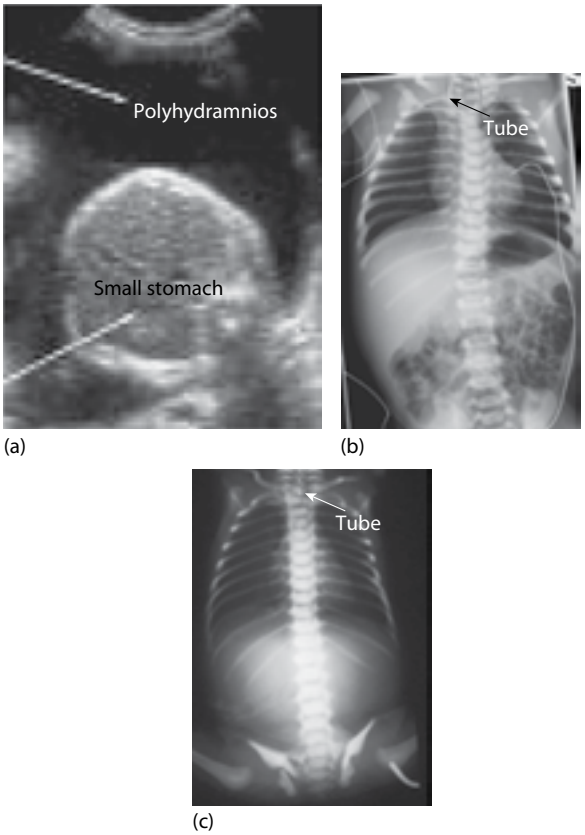

Figure 6.7 **(a)** Prenatal imaging of suspected TOF with polyhydramnios and small stomach. **(b)** Plain radiograph showing esophageal pouch tube and distal gas confirming tracheoesophageal fistula with esophageal atresia. **(c)** Plain radiograph showing esophageal pouch tube and no abdominal gas, confirming isolated esophageal atresia.

sensitive, with a positive predictive value of 56%. Additional diagnostic clues are provided by associated anomalies such as trisomy (13, 18, and 21), VACTERAL sequence (vertebral, anorectal, cardiac, tracheoesophageal, renal, limbs), and CHARGE association (coloboma, heart defects, atresia choanae, retarded development, genital hypoplasia, ear abnormality). These associated anomalies are present in more than 50% of cases and worsen the prognosis; thus, prenatal karyotyping is essential. Duodenal atresia may coexist with TOF/OA. The risk of recurrence in subsequent pregnancies for isolated TOF/OA is less than 1%. Delivery is advised to be at a specialized center with neonatal surgical input.

Postnatal surgical management is dependent on the size and condition of the baby, length of esophageal gap, and associated anomalies. Primary repair of the esophagus is the treatment of choice; however, if not achieved, staged repair with upper esophageal pouch care and gastrostomy or organ replacement with stomach or large bowel are other options. Associated anomalies require evaluation and treatment.

Long-term outcomes are indicated by improved perinatal management and inherent structural and functional defects in the trachea and esophagus. In early life, growth of the child is reported to be below the 25th centile in 50% of cases, respiratory symptoms are reported in two-thirds of TOF/OA, and gastroesophageal reflux is recorded in 50% of patients. Quality of life is better in the isolated group with successful primary repair as compared to those with associated anomalies and delayed repair.

Gastrointestinal lesions

The presence of dilated loops of bowel (>15 mm in length and 7 mm in diameter) on prenatal US scan is indicative of bowel obstruction.

Duodenal atresia has a characteristic "double-bubble" appearance on prenatal scan, resulting from the simultaneous dilatation of the stomach and proximal duodenum. Detection rate on second-trimester anomaly scan is almost 100% in the presence of polyhydramnios and the double-bubble sign. However, a late trimester event may only be detected due to polyhydramnios or not detected at all. Associated anomalies are present in approximately 50% of cases, most notably trisomy 21 in 30% of cases, cardiac anomalies in 20%, and the VACTERL association (vertebral, anorectal, cardiac, tracheoesophageal, renal, and limbs).

The incidence of duodenal atresia is 1 in 5000 live births. The postnatal survival rate is >95%, with associated anomalies, low birth weight, and prematurity contributing to the <5% mortality. Temporary delay in enteral feeding occurs due to the dysmotility in the dilated stomach and duodenum.

There are many bowel abnormalities that may be noted on prenatal scanning (dilated bowel, ascites, cystic masses, hyperperistalsis, poyhydramnios, and echogenic bowel); however, none is absolutely predictive of postnatal outcome. Patients with obstruction frequently have findings (especially in the third trimester) of bowel dilatation (Figure 6.8),

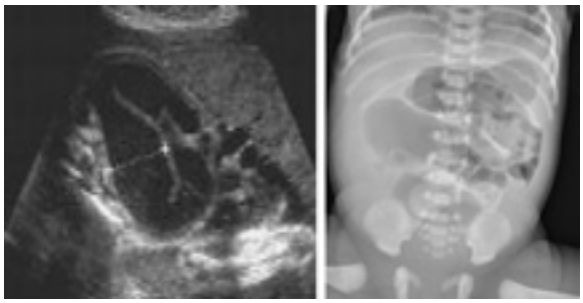

Figure 6.8 **(a)** Prenatal and **(b)** postnatal imaging of intestinal atresia.

polyhydramnios, and hyperperistalsis, but US is much less sensitive in diagnosing large bowel anomalies than those in small bowel. Since the large bowel is mostly a reservoir, with no physiologic function in utero, defects in this region such as anorectal malformations or Hirschsprung disease are very difficult to detect. Bowel dilatation and echogenic bowel may be associated with cystic fibrosis; therefore, all such fetuses should undergo postnatal evaluation for this disease. Prenatally diagnosed small bowel atresia does not select for a group with a worse prognosis, and survival rates are 95%–100%.

Abdominal cysts

Abdominal cystic lesions are not an uncommon diagnosis at antenatal US examination. A cystic mass identified in this way may represent a normal structural variant or a pathological entity requiring surgical intervention postnatally. Despite increasingly sophisticated equipment, some congenital anomalies have significant false-positive rates on US, and fetal cystic abdominal masses in particular can be difficult to diagnose accurately. Excluding cysts of renal origin, the differential diagnosis includes ovarian cysts, enteric duplication cysts, meconium pseudocysts, mesenteric cysts and choledochal cysts. Less common diagnoses include extralobar pulmonary sequestration and pancreatic, splenic, urachal, and adrenal cysts. Almost all cysts are benign, and many are self-limiting; however, these cysts create a high level of anxiety for the prospective parents, especially suspected adrenal cysts. Regular antenatal consultation and fetal counseling by the appropriate team may reduce parental anxiety levels. There is a very small role for fetal intervention. Diagnostic accuracy is greater than 90%. Resolution of these cysts was reported in 30% of cases, and of all the antenatally diagnosed cysts, 40% will come to surgical intervention. Postnatal imaging is essential (Figure 6.9).

Sacrococcygeal teratoma

SCT is the most common neonatal tumor, accounting for 1 in 35,000–40,000 births (Figure 6.10). Four types have been defined:

- Type 1—external tumor with a small presacral component
- Type 2—external tumor with a large presacral component

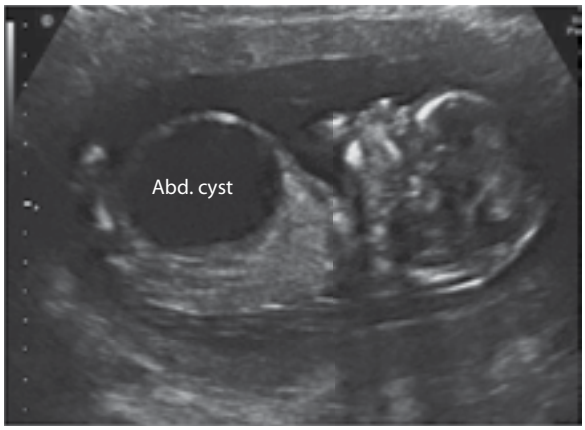

Figure 6.9 Nonspecific prenatal cyst showed complete resolution on postnatal Imaging.

- Type 3—predominantly presacral with a small external component
- Type 4—entirely presacral

The latter carries the worst prognosis due to delay in diagnosis and malignant presentation. Doppler US is the diagnostic tool; however, fetal MRI provides better definition of the intrapelvic component. SCT is a highly vascular tumor, and the fetus may develop high cardiac output failure, anemia, and ultimately hydrops, with a mortality of almost 100%. Fetal treatment of tumor resection or ablation of feeding vessel has been attempted in hydropic patients. Caesarean section may be offered to patients with large tumors to avoid the risk of bleeding during delivery. Postnatal outcomes following surgery in type 1 and 2 lesions are favorable; however, type 3 and 4 tumors may present with urological and bowel problems, with less favorable outcomes. Long-term follow-up with AFP and serial pelvic US is mandatory to exclude recurrence of the disease.

Renal anomalies

Urogenital abnormalities are among the most common disorders seen in the perinatal period and account for almost 20% of all prenatally diagnosed anomalies. The routine use of antenatal US scans has resulted in the early detection of these conditions and, in selected cases, has led to the development of management strategies including fetal intervention aimed at preservation of renal function. Two major issues are the indications for intervention in bladder outlet obstruction and early pyeloplasty in infancy in cases with hydronephrosis.

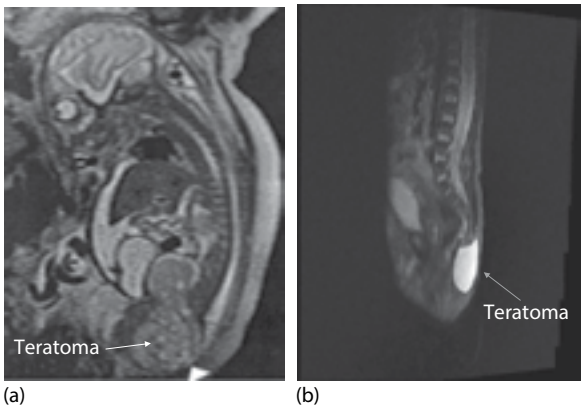

Figure 6.10 **(a)** Prenatal MRI and **(b)** postnatal image of sacrococcygeal teratoma.

Prenatal evaluation of a dilated urinary tract is based on serial US scans as well as measurement of urinary electrolytes. Ultrasonography provides measurements of the renal pelvis, assessment of the renal parenchyma, as well as detection of cysts in the cortex. In severe disease, lack of amniotic fluid may make US assessment of the renal tract difficult, and MRI may be helpful. Oligohydramnios is indicative of poor renal function and poor prognosis owing to the associated pulmonary hypoplasia. Urogenital anomalies coexist with many other congenital abnormalities, and amniocentesis should be offered in appropriate cases. It is estimated that 3% of infants will have an abnormality of the urogenital system, and half of these will require some form of surgical intervention.

UPPER URINARY TRACT OBSTRUCTION

Antenatal hydronephrosis accounts for 0.6%–0.65% pregnancies. The most common cause of prenatal hydronephrosis is pelviureteric junction (PUJ) obstruction, others being transient hydronephrosis, physiological hydronephrosis, multicystic kidney, PUVs, ureterocele, ectopic ureter, etc. The prognosis of antenatally diagnosed hydronephrosis in unilateral disease with renal pelvic diameter of <10 mm is excellent. Spontaneous resolution is noted in 20% of patients at birth and 80% at 3 years of age. Only 17% of prenatally diagnosed hydronephroses need surgical intervention. Postnatal management of hydronephrosis requires US at birth and at 1 month of age, and further evaluation with radiology and scintigraphy if an abnormality is suspected.

LOWER URINARY TRACT OBSTRUCTION

PUVs are the most common cause for lower urinary tract obstruction in boys, with an incidence of 1 in 2000–4000 live male births (Figure 6.11). The diagnosis of PUV is suspected on the prenatal US finding of bilateral hydronephrosis associated with a thickened bladder and decreased amniotic fluid volume. Serial fetal urine analysis may provide prognostic information on renal function. Prenatal diagnosis for patients with PUV is a poor prognostic sign, with 64% incidence of renal failure and transient pulmonary failure, compared to 33% in postnatally diagnosed patients. Pulmonary hypoplasia secondary to oligohydramnios largely contributes to the morbidity and mortality from fetal urethral obstruction. Outcomes of fetal intervention with vescicoamniotic shunting or fetal cystoscopic ablation of the urethral valve are still under review and await a multicenter trial.

Postnatal management includes US confirmation of the diagnosis, bladder drainage via a suprapubic or urethral route, and contrast imaging of the urethra. Primary PUV ablation, vesicostomy, and ureterostomy are postnatal

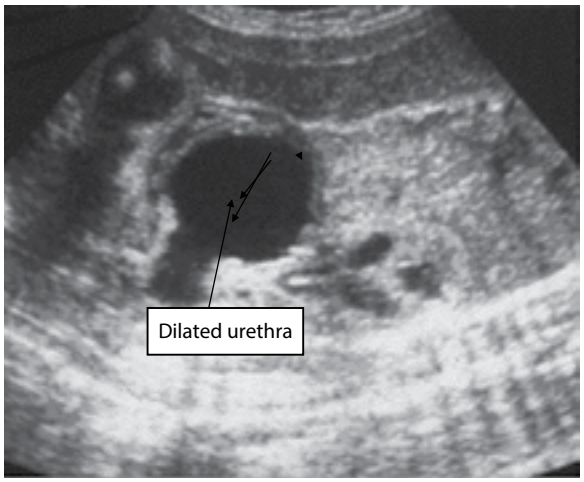

Figure 6.11 Keyhole sign of posterior urethral valves.

surgical options. The overall outcome from this disease is unfavorable.

CONCLUSION

The boundaries of pediatric surgical practice have been extended by prenatal diagnosis. The care of patients with surgically correctable defects can now be planned prenatally with the collaborative effort of obstetricians, geneticists, neonatologists, and pediatric surgeons. Essential to prenatal counseling is the understanding of the specific surgical condition's prenatal natural history, the limitations of prenatal diagnosis, the detection of associated anomalies, the risks and indications of fetal intervention programs, and postnatal outcomes. Prenatal counseling is an essential component of pediatric surgical practice and should be ensured in the training program for future pediatric surgeons.

Fetal and birth trauma

PREM PURI AND PIOTR HAJDUK

FETAL TRAUMA

Traumatic injuries in pregnancy are a major cause of non-obsterics maternal and neonatal morbidity and mortality.[1–4] About 40 years ago, it was estimated that 6%–8% of pregnant women were affected by accidental injury.[5] This number is likely to be greater now because more active lifestyles led by pregnant women in today's society may put them at increased risk of injury. When a pregnant woman presents with a major trauma, two lives are at risk. The survival of the fetus depends primarily on maternal survival,[5] but occasionally, the extent of maternal injury does not correlate with the degree of fetal injury.[1,6,7]

Treatment priorities for traumatic pregnant women remain the same as in patients who are not pregnant, although resuscitation and stabilization should be modified to account for the anatomical and physiological changes of the pregnancy.[8] The first consideration in the management of maternal trauma in an accident is to ensure the survival of the mother, as is recommended by the Advanced Trauma Life Support Program.

Assessment of the fetus forms part of the secondary survey of the mother and should be performed in conjunction with an obstetrician, because beyond 24 weeks gestational age, the fetus is potentially viable if urgent delivery is required.

Assessment of the fetus includes the following: the date of the last menstrual period, measuring the fundal height, examination for uterine contractions and tenderness, fetal movements, and fetal heart rate. An important part is the vaginal examination for amniotic fluid or blood.

Fetal distress can occur at any time and without warning. The fetus should be continually monitored to ensure early recognition of fetal distress by using the ultrasonic Doppler cardioscope. Signs of fetal distress include the following: bradycardia (<110 b.p.m.), inadequate accelerations in fetal heart rate in response to uterine contraction, and late decelerations in fetal heart rate in response to uterine relaxation.

In blunt maternal–fetal trauma, placental abruption is the leading cause of death with maternal survival.[9,10] Occasionally, minor maternal trauma may disrupt the placenta "lifeline" by shearing the relatively rigid placenta from the more elastic uterine wall, thereby leading to fetal distress and subsequent fetal death.[6] The clinical signs of placental abruption include the following: vaginal bleeding, uterine irritability, abdominal tenderness, increasing fundal height, maternal hypovolemic shock, and fetal distress. Although the common classical presentation of placental abruption involves vaginal bleeding and abdominal pain, some cases of traumatic abruption occur without these symptoms, and fetal distress may not develop for several hours.

The fetus should be considered salvageable in the face of severe or even mortal maternal injury, and more than 150 cases of successful postmortem cesarean section delivery and numerous deliveries of normal neonates just before maternal death have been described.[11,12] Fetal injuries after trauma may be treatable, but only if they are recognized. Penetrating trauma by gunshot or stab wounds, although rare,[6] is usually obvious, and thus, appropriate surgical intervention has to be undertaken (Figure 7.1a,b). Although most cases of penetrating fetal trauma are fatal to the fetus, some cases of fetal salvage have been reported.[13] In contrast, surgically treatable fetal injury may go unrecognized after blunt maternal trauma, while these injuries are much more frequent. Thus, one can recognize that after 24 weeks' gestation, cesarean section for fetal salvage is indicated in the presence of placental abruption with fetal distress or treatable life-threatening fetal injury, or if there is obvious impending or recent maternal death.

A pediatric surgeon should participate in the evaluation and management of both the pregnant patient and the neonate delivered after maternal trauma, together with the obstetrician and the neonatologist. Pregnant women should be hospitalized after trauma for appropriate evaluation and fetal monitoring, in the hope of decreasing trauma-related fetal deaths. In recent years, it is expected that every

pediatric surgeon must be familiar with the treatment of pediatric trauma. The treatment of the traumatic pregnant woman and the fetus must be part of this skill, especially if the fetus is to be considered a patient.

BIRTH TRAUMA

Birth injuries are defined as injuries associated with mechanical forces producing hemorrhage, edema, tissue disruption, or alteration of organ function occurring during the intrapartum period.[14] With the improvement in obstetric techniques, increased frequency of cesarean section in potentially difficult deliveries, decreased use of difficult forceps, and utilization of fetal heart rate and determination of acid–base status to monitor the fetus during labor, the incidence of birth injuries has decreased in recent years.[15] Furthermore, use of prenatal ultrasonography (US) has allowed early identification of the risk factors for possible birth trauma, including fetal size and position and enlarged fetal organs or masses. Nevertheless, birth injuries still occur and represent an important problem for the clinician; the incidence of birth trauma is reported to be 2–8 per 1000 live births.[16,17]

Birth injury is usually associated with unusual compressive or traction forces in association with abnormal presentation of the fetus. Factors that predispose to birth injury include primiparity, cephalopelvic disproportion, dystocia, prematurity, prolonged labor, macrosomia, abnormal presentation, forceps application, version, and extraction.[14,16,17] The newborn at greatest risk for birth injury is the one in breech presentation.

Types of birth trauma

HEAD INJURIES

Caput succedaneum

Caput succedaneum is a diffuse edematous, occasionally hemorrhagic swelling of the scalp, superficial to the periosteum, occurring secondary to compression of the presenting part during prolonged labor. Usually, caput succedaneum requires no treatment, and the swelling disappears spontaneously in a week or so. Rarely, hemorrhage into soft tissue may cause anemia that requires blood transfusion or may lead to hyperbilirubinemia, or both.[18]

Cephalhematoma

Cephalhematoma is a subperiosteal collection of blood most often found in the parietal region and sharply delineated by the surrounding suture lines (Figure 7.2). In 10%–25% of cephalhematomas there is an underlying skull fracture, which is usually of linear type and clinically unimportant.[19] The precise mechanism of production of cephalhematoma is not well established. Repeated buffeting of the fetal skull against the maternal pelvis during a prolonged labor and mechanical trauma caused by the use of forceps and vacuum extractor in delivery have been implicated as important factors. Cephalhematomas have been reported to originate in utero, antipartum. Petrikovsky et al.[20] found seven cases of cephalhematomas identified prenatally in 16,292 fetuses during comprehensive US examinations. Premature rupture of the membranes was seen and was suggested as an associated factor.

Most cephalhematomas resolve spontaneously within a few weeks. Aspiration of the hematoma is contraindicated because of the risk of introducing infection. Drainage and antibiotic therapy are only indicated in the rare case of superinfection of the cephalhematoma.[17] Occasionally, serious complications such as anemia, jaundice, abscess, septicemia, meningitis, osteomyelitis, disseminated intravascular coagulation, shock with acute hemorrhage, and depressed skull fractures have been reported in association with cephalhematomas.[14,21,22] Management involves careful observation for these complications.

Figure 7.2 Large cephalhematoma.

Skull fractures

Most of the skull fractures are linear, occurring in association with cephalhematomas and usually involving the parietal bones (Figure 7.3a). No specific treatment is required for linear fractures, but skull x-rays should be repeated when the infant reaches 2–4 months of age to rule out "growing fracture of the skull" associated with a leptomeningeal cyst (Figure 7.3b). A leptomeningeal cyst can occur rarely if the trauma causing the linear fracture tears the underlying dura, thereby permitting herniation of the meninges and brain. This requires surgical intervention to avoid progressive brain damage.[23]

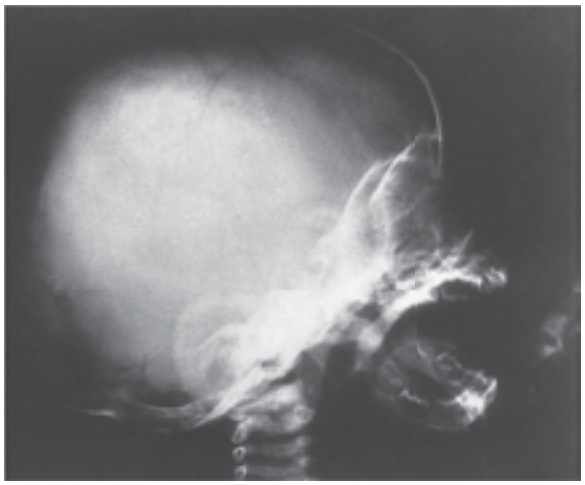
Depressed skull fractures are most often caused by pressure of the fetal head against the maternal pelvis or in association with forceps delivery (Figure 7.4). In babies with no abnormal neurological signs, expectant treatment has been associated with spontaneous resolution.[24] Several nonsurgical techniques for elevation of depressed skull fracture in the newborn have been described, including suction with a breast pump or vacuum extractor, and by digital manipulation. Fracture reduction by neurosurgical elevation should be considered when the depth is more than 2 cm.[25] Indications for surgical elevation of depressed skull fracture include the following[24]:

1. Radiographic evidence of bone fragments within the brain
2. Neurological deficit
3. Signs of increased intracranial pressure
4. Failure to elevate the fracture by closed manipulation

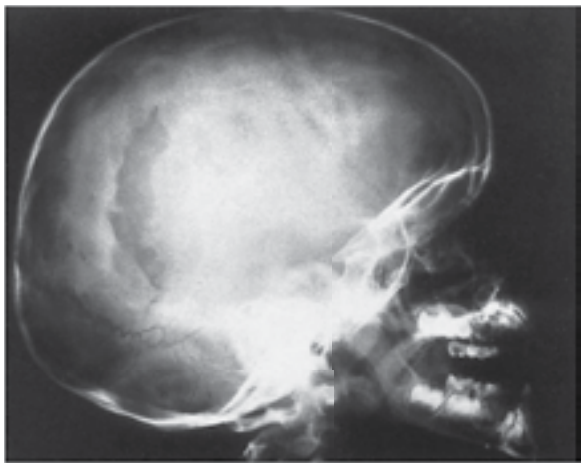
Intracranial hemorrhage

Intracranial hemorrhage following birth trauma may occur in the epidural space, the subarachnoid space, or the subdural space, or within the brain.

Epidural hemorrhage in newborns is rare, typically associated with an instrument-assisted vaginal delivery. A linear skull fracture accompanies neonatal epidural



(a)



(b)

Figure 7.3 **(a)** Linear fracture of left parietal bone at birth. **(b)** Three years later, the patient presented with a pulsatile swelling in the left parietal region. X-ray shows an extensive bone defect due to leptomeningeal cyst.

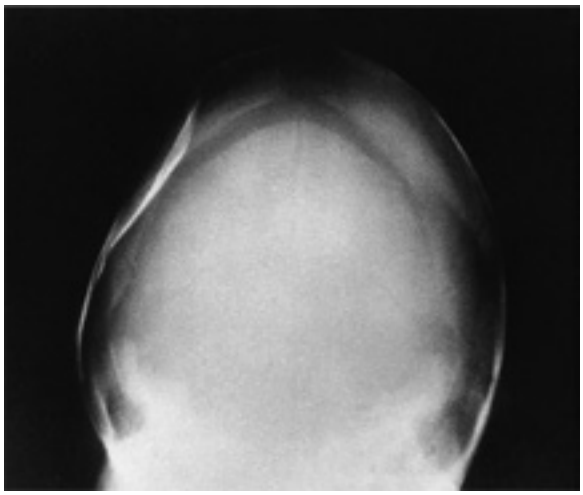


Figure 7.4 Depressed fracture of right parietal bone following forceps delivery.

hemorrhage in the majority of cases and may be associated with a cephalhematoma. As in adults, there may be a delay in the onset of symptoms. The classically described middle meningeal artery laceration from the temporal bone fracture does occur, but neonatal epidural hemorrhage may also be caused by a sinus or vein injury. Treatment of the neonatal epidural hemorrhage is dependent on prompt recognition and typically requires surgical intervention.[26]

Subarachnoid hemorrhage is the most common form of birth-related traumatic intracranial hemorrhage in the newborn.[19] Blood in the subarachnoid space can be documented by lumbar puncture and the diagnosis confirmed by computerized tomography (CT) scan. In the vast majority of cases, traumatic subarachnoid hemorrhage is benign and does not require any treatment. Occasionally, it may result in a communicating hydrocephalus. Subdural hemorrhage is caused by rupture of the cerebral veins bridging the subdural space, occurring as a result of excessive molding of the baby's head during labor or delivery. Most subdural hematomas are infratentorial and bilateral, but occasionally, they have been described in the posterior fossa. Principal factors that predispose to the occurrence of subdural hematoma include large-size infants,[19] breech delivery,[27] and forceps extraction in primiparous women.[28] Clinical features of neonatal subdural hemorrhage may include pallor, vomiting, irritability, seizures, unequal pupils, drowsiness, hypotonia, high-pitched cry, tense fontanelle, and retinal hemorrhages. The diagnosis is confirmed by a subdural tap, CT scan (Figure 7.5), or magnetic resonance imaging (MRI).[29] Although US is a standard practice for detecting germinal matrix hemorrhage in the preterm neonate,[30] it is unlikely to be as accurate as a CT scan in diagnosing peripheral lesions in subarachnoid or subdural space.[31] MRI imaging in general has high sensitivity for intracranial hemorrhage and, with its lack of ionizing radiation, is a favorable technique for the further evaluation of birth trauma over CT, especially for a neonate.[32,33] The treatment consists of repeated tapping of the subdural space using a 20-gauge needle at the lateral margin of the anterior fontanelle. In most cases, subdural collections can be treated successfully with repeated taps. Rarely, membrane stripping or subdural space shunting may be required to deal with persistent subdural collections.

Figure 7.5 CT brain scan without intravenous contrast medium in a newborn, showing blood in the subarachnoid space (large white arrow) and blood in the floor of the fourth ventricle (small white arrow).

Intracerebral hemorrhage

Traumatic intracerebral hemorrhage is the least common intracranial hemorrhage in the newborn.[19] The clinical features are those of increased intracranial pressure. The diagnosis can be made with cerebral US, CT scan, or MRI, and regression or complications can be monitored with serial studies.[29]

SPINAL CORD INJURIES

The incidence of birth injury to the spinal cord is difficult to determine because most neonatal postmortem examinations do not include complete examination of the spinal cord.[34] The leading cause of neonatal spinal cord injury is delivery of the fetus with marked hyperextension of the neck in a breech presentation. Approximately 75% of reported spinal cord injuries occurred in infants delivered vaginally in breech presentation.[35] Other predisposing factors are prematurity, shoulder dystocia, intrauterine hypoxia, and precipitous delivery.[36] The application of compressive forceps to the fetal spine during fundal pressure to relieve shoulder dystocia has been reported to result in lower thoracic spinal cord injury in the newborn.[37] The site of spinal cord injury following breech delivery is usually in the lower cervical and upper thoracic region, while injury following vertex presentation is usually located in the upper or midcervical level.[19] The injury is usually caused by stretching of the cord and not by compression. The most common mechanism responsible for spinal cord injury is the use of excessive longitudinal traction on the trunk while the head is still engaged in the pelvis.[38] The spinal cord is relatively inelastic compared with the vertebral fracture or dislocation, or both, and cord transection.

The clinical manifestations of spinal cord injury may fit into one of the following four recognized groups, depending on the severity of the damage incurred[21,39]:

1. Babies who are stillborn or die immediately after birth due to a high cervical or brainstem lesion
2. Neonates who die shortly after birth due to respiratory depression and complications and who generally have upper cervical and midcervical lesions

3. Long-term survivors who have flaccid paralysis in the neonatal period and proceed to develop spasticity and hyperreflexia in the ensuing months
4. Those with minimal neurological signs or spasticity who are often classified as having cerebral palsy[40]

The symptoms in these patients result from partial spinal cord injury or cerebral hypoxia.

When spinal cord injury is suspected, definition of the underlying pathology can be difficult using standard diagnostic procedures, including plain x-ray and CT, with or without myelography. MRI, with its excellent definition and low risk of complication, is the best diagnostic tool available to evaluate clinically suspected spinal cord pathology.[41] Spinal US is a good imaging method for guiding diagnosis of traumatic spinal cord lesions.[42]

Treatment of spinal cord injuries is supportive and includes physiotherapy, braces, and urological, orthopedic and psychological care. Surgery has little to offer to patients with these types of injuries. Great emphasis should be placed on prevention of spinal cord injury in the newborn.

PERIPHERAL NERVE INJURIES

Injury to the peripheral nerves in the newborn is usually caused by excessive traction or direct compression of nerves during delivery. The nerves most commonly involved are the brachial plexus, facial nerve, and phrenic nerve.

Brachial plexus injury

With the improvement in obstetric techniques, the incidence of birth-related brachial plexus injuries has decreased considerably in recent years. The incidence of brachial plexus birth palsy is estimated to be between 0.4 and 4 per 1000 live births.[43] The injury is usually caused by traction and stretching of the plexus. All lesions occur in the plexus above the level of the clavicle and range from simple neuropraxia, classified by Sunderland[44] as grade I, to full neurotemesis when associated with root avulsion, classified as grade V. Perinatal risk factors include large-for-gestational-age infants (macrosomia), multiparous pregnancies, previous deliveries resulting in brachial plexus birth palsy, prolonged labor, breech delivery, assisted (vacuum or forceps) difficult deliveries, shoulder dystocia, and/or asphyxiated infant.[45–47] Whereas a mechanical basis for brachial plexus injury is well accepted, delivery by cesarean does not exclude the possibility of birth palsy.[43]

Brachial plexus injury has been divided into three main types depending on the site of the injury:

1. Erb's palsy, which results from injury of the fifth and sixth cervical nerve roots, is by far the most common type of injury. The affected arm hangs limply adducted and internally rotated at the shoulder, and extended and pronated at the elbow with a flexed wrist in the typical "waiter's tip" posture (Figure 7.6). The Moro, biceps, and redial reflexes are absent on the affected side. The grasp reflex is intact. These clinical findings are the result of paralysis of the deltoid, supraspinatus, infraspinatus, brachioradialis, and supinator brevis muscles.
2. Klumpke's paralysis results from injury of the eighth cervical and first thoracic nerve roots and is extremely rare as an isolated entity. The intrinsic muscles of the hand and flexors of the wrist and fingers are affected. The grasp reflex is absent. Injury involving the cervical sympathetic fibers of the first thoracic root may result in ipsilateral Horner's syndrome.
3. Injury to the entire brachial plexus results in a flaccid arm with absence of sweating, sensation, and deep tendon reflexes.

The differential diagnosis includes the following: fracture of the clavicle or humerus, traumatic epiphysiolysis of the proximal epiphysis of the humerus, and shoulder dislocation. These injuries can occur in addition to the plexus paralysis or a phrenic nerve palsy. A radiograph of the chest, shoulder, upper arm, and clavicle should be obtained. Electromyography, an exam that is difficult to perform and interpret in the newborn or the infant, currently plays a limited role in the diagnosis of brachial plexus injury. However, it may be useful in the preoperative workup, determining the extent and site of injury, and evaluating the prognosis. MRI or CT myelography of the cervical spine is a very useful exam in preoperative planning.[48–50]

Serial physical examination of children with brachial plexus injury is recommended, because it is essential to predict recovery and determine the need for additional therapeutic or surgical intervention. Passive range of motion and active muscle strength should be assessed. Assessing infants

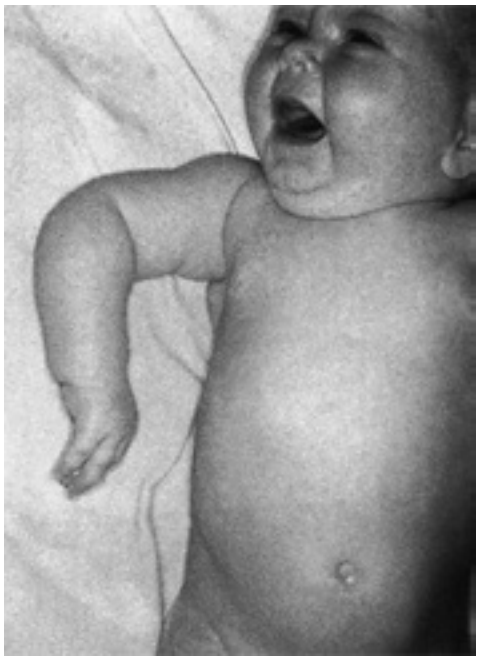

Figure 7.6 Erb's palsy. Characteristic deformity of right arm.

often requires approximation of function by observing spontaneous activity and assessing reflexes (Moro reflex, asymmetric tonic neck, and symmetric tonic neck). Most authors agree that brachial plexus lesions are most often transitory, with 75%–95% of cases advancing to complete recuperation.[51–53] The most recent studies report a lower rate of 66%, with a residual deficit in 20%–30% and considerable alteration of function in 10%–15% of cases.[45,52,54] Total paralysis and the presence of Horner's syndrome are the main factors announcing a poor prognosis.[50] The main principle of management is to maintain the range of "motion" in the affected joints. Treatment should be delayed for a period of 2 weeks after the trauma, in which immobilization of the hand and stretched nerve fibers will allow a spontaneous cure. During the first 2 weeks, the arm has to be adducted to the thorax. Abduction and external rotation position of the shoulder must be prevented due to considerable tension on the brachial plexus in that position. In the other joints, careful passive physiotherapy should be carried out. Thereafter, gentle range-of-motion exercises to shoulder, elbow, wrist, and small joints of the hand may have to be started.

The prognosis of brachial plexus paralysis is better in the Erb's patient than in the patient with Klumpke's variety and, in both of these groups, is better than in total paralysis. In the majority of Erb's palsy cases, a partial or complete recovery can be achieved.[55] Surgical exploration and repair of brachial plexus birth injuries are recommended only when there is no recovery of the biceps by 3 months of age. An electromyography and MRI or myelogram with CT scanning are performed preoperatively.[48,50] Advances in microsurgical techniques and reconstruction of the injured plexus by grafting from the sural nerve can significantly improve the functional result.[48,56,57] Recent use of synthetic collagen nerve conduits has shown very good results in select short-segment brachial plexus repairs.[58] The advantages of synthetic grafts over conventional autologous grafts include eliminating donor site morbidity, increasing the amount of graft material available, and providing direct conduits for neural growth factors produced by the proximal segment to reach the distal segment.

Facial nerve injury

Facial palsy secondary to birth trauma is usually unilateral and most commonly follows compression of the peripheral portion of the nerve, either near its emergence from the stylomastoid foramen or where the nerve transverses the ramus of the mandible. The mechanism of injury is usually either direct trauma from forceps or compression of the side of the face and nerve against the sacral promontory. The affected infant has absent or decreased forehead wrinkling, a persistently open eye, a decreased nasolabial fold, and flattening of the corner of the mouth on the affected side (Figure 7.7). Treatment is conservative, since spontaneous recovery occurs within 1 month in most cases of birth-related facial palsy.[17,47] Initial treatment should be directed at protecting the corneal epithelium from drying with the use of methylcellulose drops instilled every 4 hours. Rarely, there is a need for surgical intervention and neurolysis or a nerve cable transplant for the injured or degenerative facial nerve, after confirming the diagnosis by electromyographic and electroneurographic tests.[59]

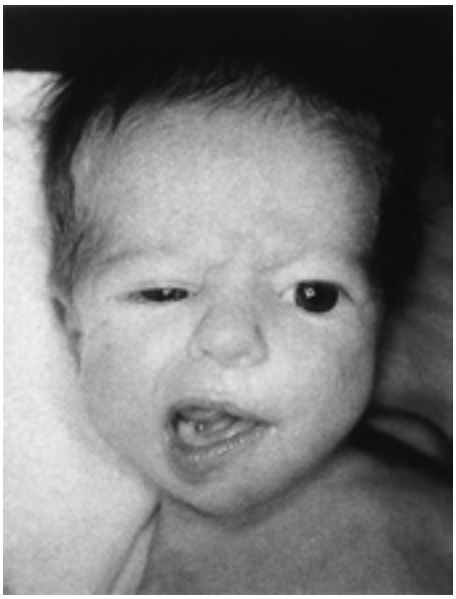

Figure 7.7 Left facial nerve palsy following difficult forceps. Note obliteration of left nasolabial fold with typical deformity of mouth and wide-open left eye.

Phrenic nerve injury

Diaphragmatic paralysis in the neonate results from stretching or avulsion of the fourth and fifth cervical roots, which form the phrenic nerve. The most common cause of phrenic nerve injury is a difficult breech delivery. The majority of injuries are unilateral with right-side dominancy (80%). Bilateral diaphragmatic paralysis is rare. Approximately 78% of cases of birth-related phrenic nerve injury have an associated brachial plexus injury.[60–63]

The clinical features of diaphragmatic paralysis are nonspecific and include respiratory distress with tachypnea, cyanosis, and recurrent atelectasis or pneumonia. Chest x-ray demonstrates an elevated hemidiaphragm about two intercostal spaces higher than the adjacent diaphragm (Figure 7.8a). Diagnosis is confirmed on fluoroscopy, which shows an immobile diaphragm or an abnormal elevation of the diaphragm during inspiration constituting paradoxical movement. Real-time US can also be employed to diagnose phrenic nerve paralysis and can be performed in the intensive care unit in very young babies (Figure 7.8b).

Initial supportive management usually includes mechanical ventilation, oxygen, chest physiotherapy, antibiotics, and nasogastric tube feedings to avoid failure to thrive and to ensure weight gain. Some patients who have severe or increasing respiratory distress may be managed by continuous positive airway pressure (CPAP).[61,62]

Most infants with diaphragmatic paralysis make a complete recovery after conservative treatment (Figure 7.8c).

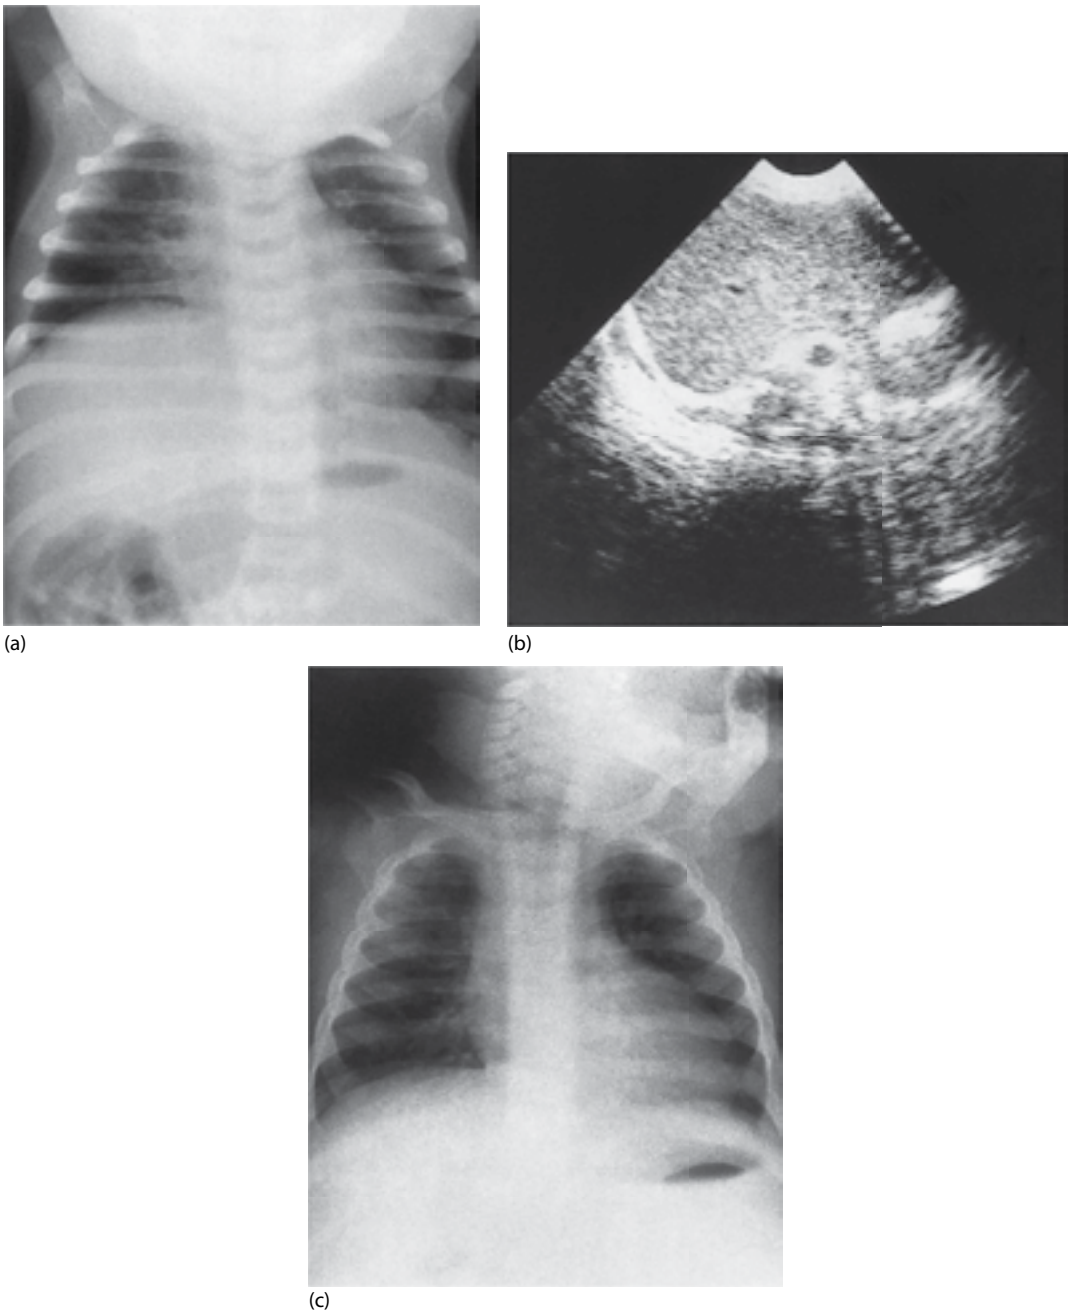

Figure 7.8 Phrenic nerve paralysis. **(a)** Chest radiography shows elevated right diaphragm. **(b)** Transverse real-time sonogram showing blurring in the region of left diaphragm due to respiratory movement. Right diaphragm did not move and is sharply outlined along the liver. **(c)** Chest x-ray 3 months later shows normal right diaphragm after conservative treatment.

Surgery may be required if there is persistent paralysis after 2 weeks of mechanical ventilation or 3 months of medical treatment. However, a recent finding showed that spontaneous recovery was limited after 1–2 months of age, suggesting that early surgical intervention is necessary to obtain a complete resolution of respiratory failure and to gain enough space for subsequent lung development.[61–63] The procedures employed include plication of the diaphragm via thoracoscopy or thoracostomy[61] or incision and replacement of the diaphragm.[64]

INTRA-ABDOMINAL INJURIES

Birth trauma involving intra-abdominal organs is relatively uncommon. The organs most commonly involved are the liver, spleen, adrenal, and kidney.

Liver

The liver is the most commonly injured abdominal organ during the birth process. Factors that predispose to liver trauma include breech presentation, infants with hepatomegaly, large infants, prematurity, and coagulation

disorders.[17] The mechanism of birth-related liver injury is thought to be either (1) thoracic compression and pulling of the hepatic ligaments with consequent tearing of the liver parenchyma or (2) direct pressure on the liver leading to subcapsular hemorrhage or rupture.[17]

Hepatic trauma more commonly results in subcapsular hemorrhage than actual rupture of the liver. The infant with subcapsular hemorrhage usually appears to be normal for the first 3 days of life, when the capsule ruptures and there is extravasation of blood into the peritoneal cavity. This is followed by sudden circulatory collapse, abdominal distension and a rapid drop in the hematocrit value. If the processus vaginalis is patent, blood may be seen in the scrotum, suggesting hemoperitoneum. In patients with primary rupture of the liver, major intraperitoneal bleeding occurs immediately, resulting in severe shock and abdominal distension. Abdominal radiographs are not usually very helpful but may show uniform opacity of the abdomen, indicating free intraperitoneal fluid. Abdominal US may confirm the diagnosis and is also useful in differentiating a solid liver tumor from an unruptured subcapsular hemorrhage. A CT scan is recommended, only if the patient is hemodynamically stable (Figure 7.9a–d). Immediate management consists of blood transfusion to restore the blood volume and recognition and correction of any coagulation disorder. This is followed by an immediate laparotomy, with evacuation of the hematoma and repair of any laceration by sutures or by fibrin glue.[65]

Spleen

Rupture of the spleen in the newborn occurs much less often than does rupture of the liver. The predisposing factors and mechanism of injury are quite similar to those of rupture of the liver. Although splenomegaly increases the risk, the vast majority of splenic injuries occur in a spleen of normal size.[66] The presenting features are cardiovascular collapse and abdominal distension. Abdominal radiographs may indicate free fluid in the peritoneal cavity. US scan and abdominal and pelvic CT are recommended to confirm diagnosis.

Nonoperative management of pediatric splenic injuries is now recognized as the treatment of choice in most of the cases. This typically involves following vital signs, serial hematocrits, and physical examination. Blood transfusions are administered as required. Hemodynamically unstable newborns usually with immediate massive hemorrhage may require exploratory laparotomy. In recent years, repair of the spleen has been advocated because of the risk of subsequent serious infections following splenectomy. Since there is a critical mass of the spleen, which prevents overwhelming postsplenectomy infection (OPSI),[67,68] every surgeon should do the utmost to preserve as much of the injured spleen as possible. Fibrin glue, splenorrhaphy, and partial splenectomy are the preferred surgical procedures.[17,69–71] This conservative surgical approach is advocated not only because of the OPSI but also because of the absence of regeneration of the injured spleen after partial splenectomy, which has been proven in animals.[72]

Adrenal

Neonatal adrenal hemorrhage occurs most commonly following a prolonged and difficult labor, culminating in a traumatic delivery. Other contributing factors include asphyxia, prematurity, placental hemorrhage, hemorrhagic disease of the newborn, septicemia, renal vein thrombosis, increased vascularity, and congenital syphilis.[73–78] The right adrenal is involved in over 70% of cases, with bilateral involvement in 5%–10%.[79,80] The presenting features vary with the degree of bleeding. The classical adrenal hemorrhage usually presents between birth and the fourth day of life as an abdominal mass with fever and jaundice or anemia.[78] The differential diagnosis may include adrenal cyst, neuroblastoma, and Wilms' tumor. Diagnosis of neonatal adrenal hemorrhage may be confirmed with a combination of US and CT. Sonography would reveal a suprarenal mass that initially is echogenic and subsequent changes to a cyst-like structure probably indicating fragmentation of the clot (Figure 7.10a,b). A "rim" suprarenal calcification may be seen on abdominal radiographs 2–4 weeks after hemorrhage.[73,81]

In patients with retroperitoneal hemorrhage, treatment consists of blood transfusion, close observation, and follow-up US studies. In infants with massive intraperitoneal hemorrhage, surgical intervention consists of laparotomy, evacuation of hematoma, ligation of bleeders, or adrenalectomy if indicated. It must be remembered that the underlying pathology may be a neuroblastoma,[82,83] and a biopsy should always be taken. Infrequently, a suspicion of an adrenal abscess ensues. In such a situation, a drainage procedure must be performed either percutaneously with US guidance or by operative exploration.

Kidney

Birth-related trauma is rare. Rupture of the kidney in the newborn is usually associated with an underlying congenital anomaly.[84] The presenting signs are hematuria and renal mass. CT is the modality of choice in the evaluation of renal injuries. Renal US may demonstrate renal rupture (Figure 7.11) or ascites. It plays an important role during the follow-up period. Treatment consists of conservative management if possible. Only in cases of severe bleeding or a total rupture of parenchyma or pelvis is a laparotomy indicated, with the correction of underlying congenital anomaly whenever it is necessary.

BONY INJURIES

Fractures due to birth trauma almost always involve the clavicle, humerus, or femur. Epiphyseal separations usually involve upper and lower humeral and upper femoral epiphyses. Dislocations caused by birth trauma are rare.

Fracture of the clavicle

Fracture of the clavicle is the most common fracture in the newborn, usually occurring during a difficult delivery associated with large infants, breech presentation, and shoulder

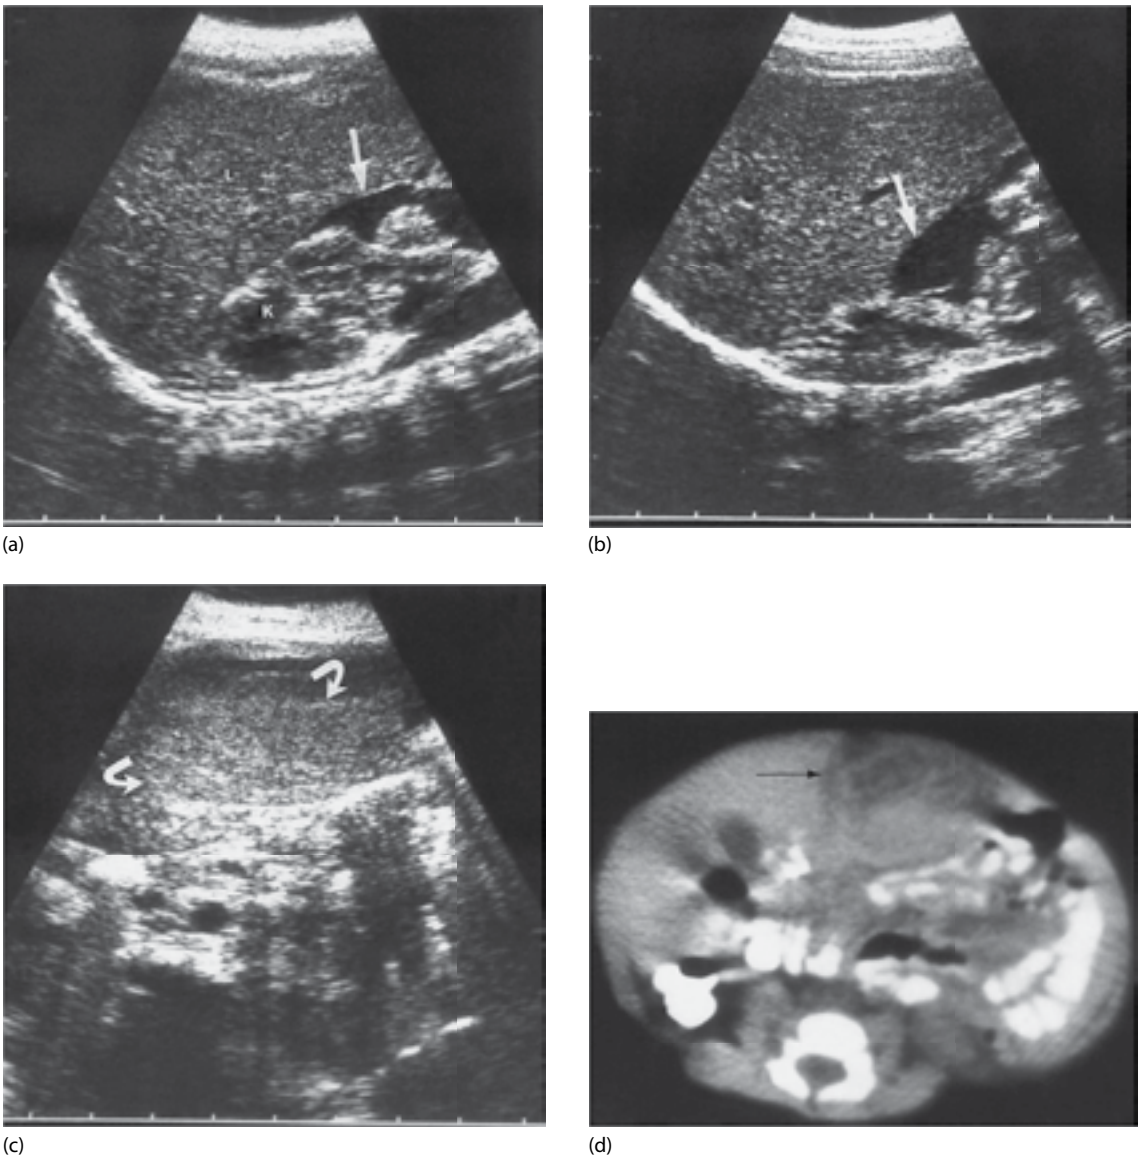

Figure 7.9 Newborn who developed a distended abdomen postdelivery. **(a,b)** Sonographic scan at 36 hours shows echo-poor material due to fresh hemorrhage (white arrow) between the anterior aspect of the right kidney (K) and the inferior aspect of the right lobe of the liver (L). **(c)** Scan through left lobe of liver demonstrating an area of increased echogenicity in keeping with hemorrhage at site of laceration (curved arrows). **(d)** Laceration in left lobe confirmed on CT scan (black arrow).

dystocia.[85] Most fractures are of the greenstick type, occurring in the middle third of the clavicle, but occasionally, the fracture is complete (Figure 7.12). Undisplaced fractures require no treatment. Fractures with marked displacement should be immobilized with a figure-of-eight bandage. Recovery is usually excellent.

Fracture of the humerus

Fractures of the humerus usually occur in the middle third of the shaft and are either transverse or spiral. They are usually greenstick fractures, but occasionally, complete fracture with overriding of fragments may occur. The most common mechanisms responsible for fracture are believed to be traction on the extended arm in the breech presentations and axillary traction to disengage an impacted shoulder in vertex presentations. Treatment consists of strapping the arm to the chest. Complete healing of the fracture fragments usually occurs by 3 weeks.

Fracture of the femur

Femoral shaft fractures usually occur in the middle third and are transverse. The injury usually follows a breech delivery. X-ray invariably shows overriding of the fracture fragments. Treatment consists of Bryant's traction for 3–4 weeks. The prognosis in femoral fractures is usually excellent.

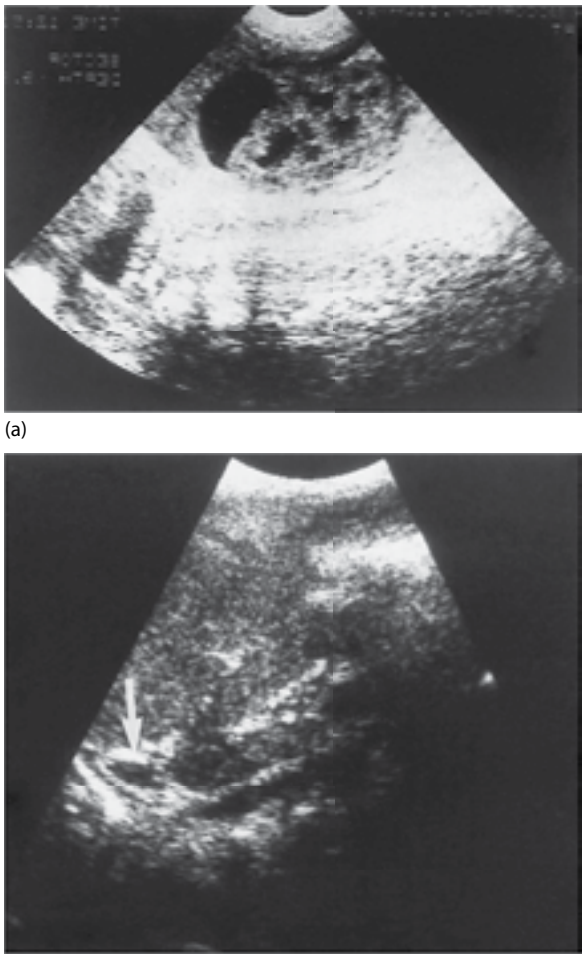

Figure 7.10 **(a)** Right suprarenal echo-poor mass representing a right adrenal hemorrhage (between cursors) in an infant who suffered birth asphyxia. **(b)** Scan performed 1 month later, showing that hemorrhage has almost cleared. Small residual echo-poor area persists (white arrow).

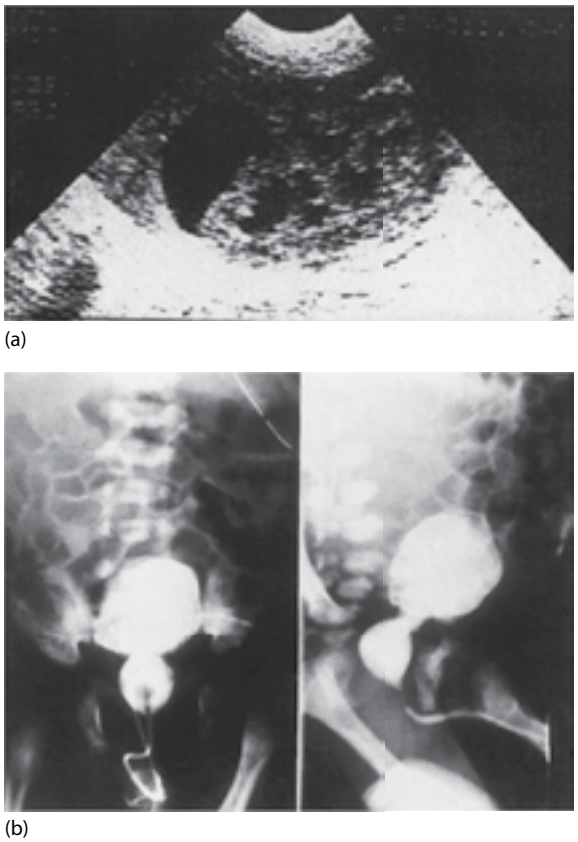

Figure 7.11 **(a)** Longitudinal sonogram showing an echolucent area in upper pole of right kidney consistent with an intracapsular rupture. Both ureters were hydronephrotic with dilated bladder on sonography. **(b)** Voiding cystogram in the same patient confirmed posterior urethral valves.

Figure 7.12 Fracture of right clavicle. Typical fracture of middle third of clavicle following forceps delivery.

Epiphyseal separations

The epiphyseal separation or fracture occurs through the hypertrophied layer of cartilage cells in the epiphysis. The most common cause is a difficult breech delivery.[86] A fracture through the proximal epiphyseal plate of the humerus is the most common epiphyseal cartilage injury. Fractures entirely confined to the epiphyseal cartilage cannot be demonstrated radiologically. However, in many cases, the fracture extends through a part of the metaphysis, separating a tiny bony fragment. This fragment is attached to the epiphysis, and if no displacement of the epiphysis has occurred, the fragment may be the only radiographic evidence of fracture. An increased distance of the metaphysis from the joint compared with the opposite side can also indicate fracture through the epiphyseal plate. After 1–2 weeks, a callus becomes visible, confirming the nature of the injury. Diagnosis at the initial stage has to be made primarily on clinical findings of pain on passive motion, swelling, and impaired movement around the joint. Recent reports suggest that epiphyseal separation can be studied by sonography and without the common use of arthrography.[86,87] Treatment of a fracture of the proximal epiphysis of

the humerus consists of immobilization of the arm by the side with a sling in 90° flexion.

Epiphysiolysis of the proximal femur is sometimes confused with congenital dislocation of the hip and septic arthritis, and can occur not only after normal delivery but also after delivery by cesarean section.[88] Treatment for a fracture of the proximal epiphysis of the femur is by traction and spica cast for 2 months.

TRAUMA TO THE GENITALIA

Breech delivery is the most common cause of tissue injuries involving the external genitalia. Edema, ecchymoses, and hematomas of the scrotum or the labia majora can occur. No treatment is needed. Spontaneous resolution of edema occurs within 24–48 hours and of discoloration within 4–5 days.

If the tunica vaginalis is injured and blood fills its cavity, a hematocele is formed. The differential diagnosis should include neonatal torsion and patent processus vaginalis.[89,90] An iatrogenic injury to the scrotum with resultant castration during breech extraction has been reported.[91]

Transport of the surgical neonate

PREM PURI AND JULIA ZIMMER

INTRODUCTION

The successful outcome of an operation performed on a newborn with congenital anomalies depends not only on the skill of the pediatric surgeon, but also on that of a large interdisciplinary team consisting of neonatologist/pediatrician, anesthetist, radiologist, pathologist, biochemist, nurses, and others necessary for dealing satisfactorily with the newborn subjected to surgery.

The pediatric transport team is a natural physical extension of the neonatal or pediatric intensive care unit and should be able to provide advanced critical care management for children at remote sites and during transport to a tertiary center.[1] Advances in neonatal intensive care dictate that effective and efficient treatment of the sickest neonates can only be available by concentrating resources such as equipment and skilled staff in a few specialist pediatric centers that have responsibilities to a particular region.[2] There has been a marked change in the last two decades with regard to the knowledge, capabilities, and delivery of neonatal transport.[3,4] Neonates with congenital malformations will therefore have to be transported safely to these centers, sometimes over considerable distances.

PRENATAL TRANSFER

Nowadays, it is general consensus that the best and safest way to care for both the mother and the newborn is the transfer of the pregnant woman before delivery to a high-risk perinatal center.[2] Several studies support this *in utero* transportation of the high-risk fetus, particularly for extremely preterm and very-low-birth-weight (VLBW) babies and those with life-threatening neonatal surgical problems.[5–9]

Hypothermia remains a main problem in these babies as it adversely affects neonatal outcome, and poor posttransfer temperature seems to be an independent predictor of mortality.[10,11]

PRETRANSFER MANAGEMENT

Transferring a newborn without proper stabilization is associated with increased morbidity and mortality. The golden rule is still that no neonate should be transported unless his/her condition has been sufficiently stabilized to survive the expected duration of the journey.[8] Nevertheless, studies have shown show that, regardless of their clinical status, a high percentage of referred neonates suffer deterioration during transport, resulting in a higher risk of early neonatal mortality.[10] Therefore, precaution and careful attention to pretransfer management will provide a higher margin of safety during the journey, especially as the transport environment is usually noisy and the access to the patient is restricted, leading to potential difficulties in providing adequate treatment should problems arise.[12] All babies must be properly resuscitated before the journey is undertaken.[2,8] All drugs, fluids, and equipment that are necessary for transfer should be carried by the transport team (Table 8.1).[13]

Airway management

It should be ensured that the airway is clear, that the baby is well oxygenated, and that ventilation can be maintained during transport. If any risk for deterioration of spontaneous breathing is present, the child should be intubated before departure,[12] as emergency intubation while travelling is often difficult or hazardous. Except in patients with a fractured base of the skull, nasal obstruction, or significant coagulopathy, every child should be intubated nasotracheally.[13] All intubated patients need to be suctioned regularly.

Temperature regulation

Thermoregulation requires critical attention. Hypothermia causes an increase in the neonate's metabolic rate with a subsequent increase in glucose and oxygen use ensuing

Table 8.1 Transfer equipment for neonatal transports

acidosis and if not reversed, persistent pulmonary hypertension of the neonate develops.[7] Neonates are unable to maintain thermogenesis through shivering, and their heat-producing mechanism is limited to metabolism of brown fat and peripheral vasoconstriction.[11,14] Hypothermia with a core body temperature below 36.4°C (97.5°F) in neonates has been correlated with increased mortality.[11] This can all be avoided by warming the baby to a core temperature of at least 36.5°C and using a prewarmed transport incubator in a prewarmed ambulance.[11] Hypothermia can also occur as a sign of infection and should implicate diagnostic evaluation and antibiotic treatment if required.[14] Hyperthermia above 37°C (98.6°F) should be avoided as it is associated with perinatal depression and hypoxic brain injury.[14]

Circulation

Two reliable and secure routes of venous access should be in place. Many surgical newborns have abnormal losses of water, electrolytes, and proteins, which must be replaced to prevent hypovolemia and shock. Intravenous (IV) fluids must be initiated immediately, and sometimes, initiation of inotropic catecholamines may be warranted.[5,7,12] A urinary catheter should be inserted in any patient to closely monitor urinary output in any patient in whom there will be excessive fluid losses.

Every neonate requiring transport must have an adequately sized functioning nasogastric tube to prevent vomiting and aspiration. It should be taped securely in position and kept on open drainage or attached to a low-pressure suction pump, which should be aspirated frequently to prevent occlusion.[12] Glucose blood levels should be monitored regularly and corrected if necessary.[7]

Documentation

Furthermore, some essential data should be transferred with the infant. A copy of the infant's chart with completed medical notes, all x-rays/ultrasound scans, laboratory reports, and nursing documentation (urine output, passage of stools, eye prophylaxis, hepatitis vaccine, blood type, other medication administration) should accompany the patient. It should be clearly documented whether vitamin K was given. Prophylactic broad-spectrum antibiotics should be started if there is a risk of infection. A parental consent for operation, signed by the mother if the parents are not married, should be sent together with a contactable phone number to be able to explain to the parents the surgical condition of their child and the operative procedure. A sample of maternal blood should be sent for cross-matching, along with a cord blood specimen and a copy of maternal records (including complete maternal history and labor and delivery records).

TRANSPORT TEAM

It widely accepted that specific transport training is required by staff who will be called upon to transfer neonatal patients.[15,16] Local and individual circumstances will determine whether the referring or specialist center will send a transport team. The composition of the team may also vary from institution to institution. Ideally, the transport team consists of a transport neonatologist/pediatrician and a trained neonatal nurse familiar with and able to anticipate potential problems associated with specific lesions.[7] They should be familiar with all equipment and its function and should be experienced in stabilizing an infant in suboptimal conditions. A further option is the use of advanced neonatal nurse practitioners (ANNPs), who have been shown to provide comparable care to trainee pediatricians.[16] Some institutions have formed a nursing transport team trained and experienced in the transfer of sick neonates, guiding the doctors, and operating the equipment.[17] However, a recent Cochrane analysis has shown that there is no credible evidence from literature-based randomized trials to support or confute the benefits of specialist neonatal transport staff for neonatal outcome of morbidity and mortality.[18]

TRANSPORT VEHICLES

Selection of a transport vehicle is dependent on the distance travelled, geography, weather conditions, ground traffic, vehicle availability, size of the transport team, the nature of the infant's problem, and the need for speed.[2] Deterioration of the medical condition can be influenced by transport-related factors such as response and stabilization time or the mode of transport.[19–23]

A variety of conveyances are in popular use, including ground ambulances, helicopters, and fixed-wing aircraft. Air transport has several disadvantages. A major disadvantage is that separate ground transport must be arranged at both ends to move the baby between the airport and the hospital. The exception arises in those circumstances in which helicopter landing sites are available at both receiving and referring institutions. Vibration is not usually detrimental to the infant, but can dislodge lines and tubes and adversely

affect monitoring equipment.[24] Noise, vibration, and poor lighting make in-flight monitoring of the infant difficult in a rotary-wing aircraft (helicopter).[7,8] This problem is not experienced to such a significant degree in a fixed-wing aircraft. Overall, the noise and vibrations may cause distress and discomfort to the infant, leading to a deteriorating clinical condition, and thus, it is logical to minimize these as much as possible.[24] The transport incubator as well as the infant in the incubator himself/herself should be securely strapped in case of turbulence of the plane. Moreover, the space in a plane is limited and can cause difficulties in manipulating the airway.[7,8]

The negative effects of altitude on the neonate's body can be detrimental.[25] With increasing altitude, the partial pressure of oxygen decreases; therefore, diffusion of oxygen across the alveolar membranes becomes more difficult, resulting in decreasing oxygen saturation in the infant. To maintain the same level of oxygenation, a higher percentage of oxygen may be required. Moreover, the barometric pressure will also decrease with increasing altitude, the volume of gas will increase, and any air trapped in a body cavity will expand. This could have a dramatic effect on pulmonary function,[7] and small insignificant air leaks can become dangerous. This is particularly important in the setting of pneumothoraces, pneumoperitoneum, or intramural gas.[24] It is therefore important to ensure that all air leaks are drained if possible.

Monitoring is essential during transfer because clinical assessment can be limited due to suboptimal lighting, noise, vibration, and lack of space. Invasive and noninvasive measures of arterial pressure, pulse oximetry, electrocardiograph (ECG), core temperature measurement, and pressure transducers for central venous and intracranial pressure readouts must be present. All monitors and syringe pumps should be battery operated.[5] An appropriate stock of airway and ventilatory equipment (self-inflating resuscitation bags, masks, airways, laryngoscopes, uncuffed neonatal endotracheal tubes of various sizes, humidifiers, portable suction apparatus, oxygen supplies, etc.) as well as IV supplies, intraosseous needles, chest tubes, umbilical catheter kits, and emergency drugs should be present at any time.[7]

Because of the very different nature of air travel compared to ground travel, it is imperative that staff receive training specifically directed at both the environment and specific problems that they may encounter in each situation, including logistics (landing sites), airborne environment, and safety issues.[16]

TRANSPORT INCUBATORS

Standard requirements for transport incubators are established in an international standard.[26,27] Currently available portable incubators (Figure 8.1) are designed and equipped for transporting sick newborns.[28] The incubator is a central piece of equipment that has to provide warmth, visibility, and access. It should be able to maintain a specific

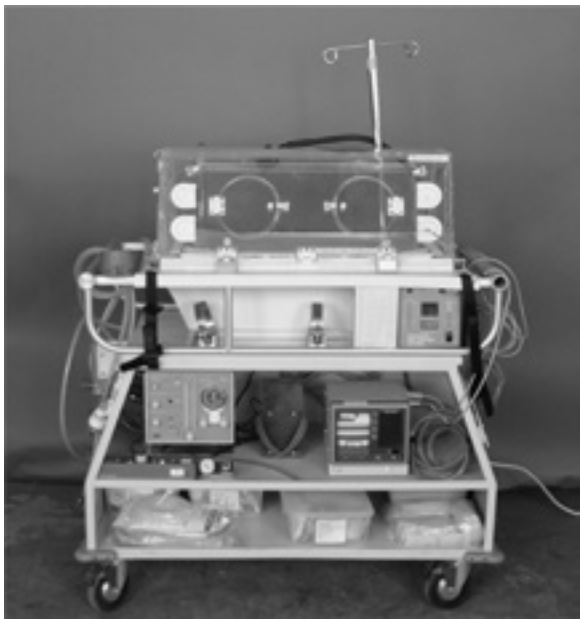

Figure 8.1 A portable incubator.

temperature under a variety of different ambient conditions (e.g., –15°C/5°F to 28°C/82°F).[26] The patient compartment of the transport incubator must be equipped with a front flap for loading and so that there is good access to the neonate in the event of an emergency.[26] It should also be able to run on batteries and must be equipped with its recharger. Guidelines state that the energy of the battery should be sufficient for a minimum of 90 minutes at an ambient temperature of 15°C/59°F.[26] It should be equipped with a cardiorespiratory monitor, pulse oximeter, infusion pump, oxygen analyzer, oxygen and air cylinders, double Plexiglas walls, and shock-absorbing wheels.[7] In the case of transporting very sick neonates and preterm babies, ventilation may be required. In these cases, the incubator should be equipped with a mechanical ventilator which is time-cycled, pressure-limited and capable of delivering conventional ventilations and constant positive airway pressure (CPAP).[26] When securing the neonate in the incubator, one must bear in mind the size of the infant, extreme sensitivity of preterm skin, reduced muscle tone, low body profile, and body weight distribution.[29]

TRANSPORT PROCEDURE

The perfect transfer does not exist yet. It involves early and effective communication between the referring and specialist center, stabilization of the baby pretransfer, and provision of special needs and care during transport.[12] All too often, transport is hastily arranged and conducted in a vacuum of communication, resulting in preventable catastrophes such as vomiting and aspiration, hypothermia, hypovolemia, and airway obstruction,[6] and in the majority of cases, most adverse events arise from poor planning and preparation. Ideally, transfer is arranged at a senior level,

i.e., a telephone conversation between a specialist pediatric registrar or consultant pediatrician in the referring center and specialist surgical registrar or consultant pediatric surgeon in the receiving center.[30]

Of increasing relevance is the so-called family-centered care during the transport procedure[31,32] as parental accompaniment has been found to be emotionally beneficial to the child and to reduce parental anxiety.[32]

RECEIVING CENTER

Continuation of care is essential to improving neonatal outcome. On arrival at the tertiary center, a brief report of prenatal, labor, and delivery history should be given by the transport team to the intensive care unit staff, together with details of the newborn's resuscitation and any problems experienced during transfer.[7] The accompanying pediatrician should review the baby and all documents together with the accepting surgeon and neonatologist/pediatrician or anesthetist, if necessary. The parents should be introduced to all staff who will be involved in the care of their baby. Every procedure should be explained in a clear and comprehensive language to avoid confusion and parental fear. The consent form should be updated if necessary. Blood tests and radiological examinations can be ordered subsequently.

SPECIAL CONSIDERATIONS

Gastroschisis

The baby with gastroschisis is at a higher risk for hypothermia, excessive fluid loss, shock, and infection due to lack of a covering peritoneal/amniotic membrane, which gives rise to exposed viscera and peritoneal surfaces. Therefore, radiant heating should be available in the room, and the baby should be kept in a warmed incubator. Intestinal strangulation, necrosis, and obstruction may also occur due to the small size of the paraumbilical defect. Treatment starts immediately after delivery in order to prevent fluid loss and hypothermia (Table 8.2). Intubation and ventilation is carried out if required, and immediate resuscitation with adequate IV fluids (minimum 120 mL/kg per 24 hours)

Table 8.2 Stabilization of a newborn with anterior abdominal wall defect prior to transfer to a referral center

Warm environment
Evaluate respiratory status

IV fluids, correct deficits
Antibiotics
Vitamin K
Urinary catheter

Figure 8.2 Gastroschisis with silo placement.

to overcome substantial water, electrolyte, and protein loss is started. Pulse rate, mean arterial pressure, and glucose level should be observed. Ensure that vitamin K is given and broad-spectrum antibiotics (ampicillin, gentamicin and metronidazole) are commenced to reduce contamination of the exposed intestinal loops. A nasogastric tube is passed for intestinal decompression and prevention of pulmonary aspiration. A urinary catheter is passed to decompress the bladder and to monitor urinary output. In many instances, the viscera are wrapped in sterile gauze that has been soaked in warm sterile saline, and then the abdomen, along with the covered defect, is wrapped in dry sterile gauze. This may, however, induce hypothermia as the gauze cools. If the gauze is allowed to dry, this may stick to the intestinal surface and cause serosal injury when trying remove it.[33] Ideally, the bowel should be placed in sterile clear plastic bag or silo (Figure 8.2). If this is not available, the bowel is localized in the center of the abdomen, and cling film is used to encircle the exposed intestine and is wrapped around the infant.[34] These measures minimize heat loss and trauma to the exposed viscera. The positioning of the infant is very important for preventing bowel ischemia. If the infant is supine and the bowel lies on one side, there is a risk of ischemia to the bowel if the superior mesenteric artery becomes kinked. Hence, the best position is a right lateral position so that the superior mesenteric artery exits straight from the defect.

Omphalocele

As with any abdominal wall defect, the care of the neonate begins with resuscitation. Initially, the respiratory

situation needs to be stabilized and the sac protected from rupture and infection, and to minimize heat loss.[34] A nasogastric tube is passed immediately to decompress the stomach and bowel. IV fluids, broad-spectrum antibiotics, and vitamin K should be started. The defect must be inspected to ensure that the sac is intact.[35] The sac should be stabilized in the middle of the abdomen to prevent kinking of the vessels and covered with a sterile, dry, nonadherent dressing to prevent trauma and heat loss. If the sac is ruptured, then the exposed bowel is treated as it is for gastroschisis.[35]

Pierre Robin syndrome

Babies with Pierre Robin syndrome carry a high risk of tongue swallowing and asphyxiation. The baby should be nursed prone to prevent the tongue from falling back into the airway and an oropharyngeal airway inserted.[6]

Choanal atresia

Neonates with choanal atresia suffer from intermittent hypoxia. The baby should be nursed with an appropriately sized and secured oropharyngeal airway with the end or teeth cut off to keep the mouth open.[12] One must ensure that the airway does not go too far into the pharynx as it may enter the esophagus and occlude the airway. In emergencies, the successful usage of larynx masks has been reported.[36]

Myelomeningocele

Infants with myelomeningocele (MMC) should be nursed prone in order to prevent trauma and pressure on the spinal area. A warm, sterile, saline-soaked dressing is placed over the lesion and cling film wrapped around the baby to prevent drying and dehiscence. If the sac is ruptured and cerebrospinal fluid is leaking, or if the MMC is open, it should be covered with Betadine- or chlorhexidine-soaked gauze and IV broad-spectrum antibiotics started. Care must be taken to prevent fecal contamination in sacral lesions.[7] Careful observation and documentation of neurological function is essential before, during, and after transport, including evaluation of the sensorimotor level and assessment of the degree of hydrocephalus.[7]

Bladder exstrophy

At birth, the umbilical cord should be ligated close to the abdominal wall and the umbilical clamp removed to prevent mechanical damage to the bladder mucosa and excoriation of the bladder surface.[5,37] Trauma and damage to the exposed bladder mucosa and plate should be avoided by covering the defect with cling film wrapped around the baby to prevent the mucosa from sticking to clothing or diapers. This will allow urine to escape while establishing a barrier between the environment and the fragile bladder mucosa. Old urine, mucus, and any detritus should be washed from the surface of the bladder with warmed sterile saline at each diaper change.[37] Prophylactic antibiotics should be started immediately.

Cloacal exstrophy

The same measurements to protect the omphalocele sac as discussed under the section "Omphalocele" are applicable.

Esophageal atresia with tracheoesophageal fistula

Most babies with esophageal atresia (EA) become symptomatic soon after birth. Symptoms include excessive drooling, coughing, or choking with the first feed. Once the diagnosis of EA is suspected, the baby should be transferred to a tertiary referral center for further investigation and surgery. Some babies will require endotracheal intubation and ventilation. These infants are particularly at risk because mechanical ventilation is relatively ineffective due to the presence of a fistula. Therefore, the tip of the endotracheal tube should be placed proximal to the carina but distal to the fistula. If the fistula is next to the carina, the fistula can be temporarily occluded with a Fogarty catheter.[38] However, urgent transfer and ligation of the fistula are essential.

Generally, the infant should be handled with care and crying avoided to reduce the risk of aspiration and abdominal distension, and thereby, respiratory distress.[5] Moreover, the baby should be well oxygenated at all times and kept in a warm environment. Regurgitation of gastric contents through the fistula during transport can be prevented by keeping the head of the baby in a slightly elevated position (30°) or nursing the baby prone or in a right lateral position and thereby decreasing the work of breathing and improving oxygenation.[5] The blind upper esophageal pouch should be kept empty. A Replogle sump catheter should be placed in the pouch and connected to low-intermittent or low-continuous suction in order to prevent accumulation of saliva. As these double-lumen esophageal tubes have a tendency to become blocked with mucus, they should be irrigated frequently during transport. IV fluids should be started to provide maintenance and supplemental fluids and electrolytes to compensate for esophageal secretion losses. Infection should be prevented and any existing pneumonitis treated by broad-spectrum antibiotics. Vitamin K should be administered prior to transfer.

Congenital diaphragmatic hernia

The initial objective for the neonatologist and anesthetist is to stabilize the critically ill neonate before transport to the referral center (Table 8.3). A nasogastric tube should be passed immediately on diagnosis to decompress the gastrointestinal tract and to prevent further compression of the lung. If congenital diaphragmatic hernia (CDH) is diagnosed

Table 8.3 Stabilization of a neonate with congenital diaphragmatic hernia prior to transport

Maintain warm environment
Nasogastric tube
Intubation and ventilation
IV fluids

Antibiotics
Vitamin K

prenatally, most centers perform endotracheal intubation and mechanical ventilation directly after birth, which helps to maintain cardiopulmonary stability and impede the natural descent into hypoxemia and hypercapnia.[39]

Full sedation and paralysis and gentle ventilation will reduce the risk of barotraumas in the setting of hypoplastic, delicate lungs. Mask ventilation should be avoided because it will distend the stomach and further compromise the respiratory status. Hyperventilation, using low pressures and high oxygen content, correction of acidosis, and prevention of thermal and metabolic stress are recommended to prevent pulmonary hypertension.[7] Some infants need high-frequency oscillatory ventilation (HFOV) when conventional ventilation proves ineffective. The rationale is that small tidal volumes and gas transport by augmented diffusion result in a lower shear stress and fewer barotraumas.[40] As there is frequently no oscillatory ventilation option available on transport ventilators, clinical teams will usually have to convert to standard ventilation for transfer.[41]

$PaCO_2$ levels and the oxygenation index can be used as a biomarker of effective CDH management,[39,42,43] and the simplified formula of blood gas (PaO_2–$PaCO_2$) in the postdelivery period can predict the need for extracorporeal membrane oxygenation (ECMO) or death.[44]

Careful attention to fluid balance with IV fluids, fresh-frozen plasma (FFP), and catecholamines, if necessary, should be started to maintain adequate peripheral perfusion without causing pulmonary overload.[40] Prophylactic antibiotics should be started and vitamin K administered. Venous access through the umbilicus is useful for obtaining mixed venous blood gas specimens and monitoring central venous pressures if passed across the liver into the right atrium. Arterial access with an umbilical artery catheter will allow monitoring of systemic blood pressure and blood gas measurements at the postductal level. The baby will also need a right radial arterial line to measure preductal blood gases, and a preductal pH ≥7.2 with an oxygen saturation of 85%–90% is acceptable.[39] This can be inserted on arrival at the referral center. Acute deterioration of the infant's condition can occur during transfer due to a pneumothorax. Equipment for intercostal drainage must be available since it can be a lifesaving maneuver.[7]

There has been tremendous growth in the use of extracorporeal life support for neonatal cardiopulmonary failure in the last decades. ECMO has been used as a salvage procedure in high-risk neonates with CHD who fail to respond to mechanical ventilation and meet entry criteria. ECMO is able to partly take over oxygenation and carbon dioxide removal, and thereby may allow respiratory settings to be adjusted to the mechanical and gas exchange properties of the diseased lung.[45] Despite the common use of ECMO for high-risk neonates with CDH, a Cochrane review found that its benefit is unclear.[46] Other studies were also unable to show a survival benefit of ECMO usage in CDH patients.[47,48]

The number of centers providing ECMO is still limited, so special services are needed to transport critically ill neonates to these clinics. Transportable ECMO systems can effectively stabilize and transport high-risk neonates to an ECMO-competent center.[49] The use of inhaled nitric oxide (NO) leads to a reduction in endogenous production of NO, but its value in patients with CDH is still controversial.[40,50] Studies have shown that there is an immediate short-term improvement in oxygenation seen in some treated infants, and this may be of benefit in stabilizing infants for transport and initiation of ECMO. However, inhaled NO did not reduce the need for ECMO.[39,51]

Intestinal obstruction

Intestinal obstruction can occur as a result of a number of conditions, e.g., malrotation, duplication of the alimentary tract, intestinal atresias, necrotizing enterocolitis (NEC), Hirschsprung disease, meconium ileus, and anorectal anomalies. The main objectives are to decompress the bowel and prevent aspiration, accurately estimate and correct fluid losses, and minimize heat loss. A nasogastric tube should be passed to minimize distension and suction carried out regularly and left on free drainage between aspirations. Serum electrolytes and proteins are sequestered in the intestinal wall and lumen, and isotonic IV fluids and colloids should be started to correct acid–base and volume deficits.[33] These must be reviewed and adjusted every 6–8 hours according to the needs of the infant. Broad-spectrum antibiotics should be started prophylactically.

Necrotizing enterocolitis

Neonates with NEC usually are transferred only if surgery is required in case of perforation of gangrenous bowel resulting in pneumoperitoneum or progressive clinical deterioration with evidence of peritonitis.[12] Usually, they are critically ill with sepsis and shock. Prompt resuscitation with crystalloids, colloids, or blood to correct acidosis is started prior to departure. Ventilation with intermittent positive pressure and inotropic support is often required.[5] Blood pressure and blood glucose must be monitored closely. A sump nasogastric tube on continuous suction is passed and suctioned regularly prior to and during transport. Broad-spectrum antibiotics to cover for gram-positive, gram-negative, and anaerobic coverage are started.[33]

CONCLUSION

The approach to the care of the high-risk newborn has changed dramatically in the last two decades. The newborn with a serious congenital malformation requires assessment and stabilization by experienced staff prior to and during transport to the regional center. Stabilization of high-risk newborns before transport is associated with a reduction in perinatal morbidity and mortality. The pediatric transport team plays a vital role in the transport of these patients to tertiary pediatric facilities. The overall aim of transport of the surgical neonate should be to bring the services of the intensive care unit to the patient's bedside during transport to a specialist center.

Specific risks for the preterm infant

EMILY A. KIERAN AND COLM P. F. O'DONNELL

INTRODUCTION

Approximately 5%–18% of babies are born preterm (i.e., before 37 weeks of completed gestation) worldwide. Prematurity affects about 7%–12% of births in developed countries.[1,2] In the United Kingdom, an estimated 10% of infants are delivered prematurely and 12% in the United States.[2] The World Health Organization divides preterm infants into three subcategories based on gestational age: extremely preterm infants born at <28 weeks; very preterm infants born at 28–31 weeks and 6 days gestation; and moderate to late preterm infants born at 32–37 weeks.[1] In developed countries, prematurity is the leading cause of neonatal mortality, and preterm babies are at a greater overall risk of morbidity and long-term adverse outcomes than infants born at term.[3,4] Extremely preterm infants are at highest risk; and the chances of survival without long-term sequelae increases with increasing gestation at birth.[5] Advances in the care of extremely preterm infants over the last decades have increased rates of survival, and published data show improved outcomes for these infants. However, with medical advances, infants are surviving from much earlier gestations, and therefore, we still see poor outcomes with a high rate of long-term neurodevelopmental problems.[5–7] The reasons why infants are born preterm vary. Some preterm infants are delivered spontaneously, while others are delivered early because obstetricians identify conditions that pose risks to the mother (e.g., preeclampsia) or fetus (e.g., growth restriction due to placental insufficiency). The proportion of preterm infants whose delivery is planned is greater in developed than in developing countries and has increased in developed countries over time. This is likely due to improved antenatal care identifying risks to the mother and the fetus, and also because the improved outcomes for preterm infants mean that early delivery is not now the "death sentence" that it once may have been.

Preterm infants differ from term infants in size and appearance as the major period of in utero growth is in the third trimester of pregnancy (weeks 28–37). Birth weight is the measure most commonly used to express the size of an infant and to record growth over time. It is also used to describe categories of infants born prematurely (low birth weight [LBW] <2500 grams; very low birth weight [VLBW] <1500 grams; extremely low birth weight [ELBW] <1000 grams).[8]

When infants are born prematurely, their various organs and body systems have had less time to develop in utero. After birth, the preterm infant has to adapt to extrauterine life while also ensuring the ongoing development and maturation of the organs that should have continued in utero during the third trimester of pregnancy. Preterm infants can experience difficulties affecting all body systems at various stages during their stay in the neonatal intensive care unit (NICU).

GENERAL

Preterm infants often need support immediately after birth. A pediatric team should be present in the delivery room for every anticipated preterm delivery. The number of staff and experience required depend on the gestational age, birth weight, and number of infants, with more and more experienced staff needed for more immature babies, smaller babies, and multiple births.

Due to a combination of their low birth weight, large ratio of body surface area to mass, thin fragile skin, and relatively low percentage of insulating brown fat, preterm infants are at risk of heat loss and hypothermia. Newborn infants' total body water content is much higher than that of older children and adults. Preterm infants, with their thin fragile skin, lose water by evaporation through the skin. Immediately after birth, extremely preterm infants are often placed under a radiant heat source and in a polyethylene (food-grade clear plastic) bag or wrap to minimize evaporative heat losses. On admission to the NICU, they should be cared for in a neutral thermal environment, ideally in a prewarmed, closed incubator, until they are mature enough to maintain their own temperature in ambient room temperature in an open cot. Extremely preterm infants

are most at risk of water loss and should be cared for in humidified incubators to minimize water loss by evaporation. Preterm infants should only be cared for on an open exposed surface under radiant heat if easy access is required e.g., for procedures such as central vascular catheter (CVC) insertion.

Preterm infants, in particular ELBW infants with intrauterine growth restriction (IUGR), are at increased risk of developing hypoglycemia compared to term infants. They should have their blood sugar level (BSL) checked on admission to the NICU and should be commenced on a dextrose containing intravenous solution as soon as possible to maintain BSL in an acceptable range, ideally >2.6 mmol. Prolonged symptomatic hypoglycemia may lead to long-term neurodevelopmental consequences.

RESPIRATORY

Respiratory distress syndrome

The most common respiratory disorder that preterm infants experience is respiratory distress syndrome (RDS). RDS was originally called hyaline membrane disease (HMD) due to the characteristic appearance of inflammatory exudates (*hyaline membranes*) seen on histopathological examination of postmortem lung specimens of preterm infants who died from hypoxic respiratory failure. RDS is caused by the combination of structural lung immaturity and a deficiency in the production and function of surfactant in the preterm lung. Alveolar development and native surfactant production in the lungs occur from 23 weeks gestation and continue into early childhood. The more premature an infant is born, the higher his/her risk of developing RDS, and the more severe the course may be.

Clinical signs of RDS develop within the first few hours and worsen over the first 48–72 hours of life. Babies may die from their lung immaturity within this time, or their signs may gradually improve thereafter. The typical clinical features of RDS are tachypnea (>60 breaths per minute); expiratory grunting; intercostal, subcostal, and sternal recessions; nasal flaring; and cyanosis and low oxygen saturations. These may be further complicated by apnea and bradycardia. The structural and functional immaturity of the preterm lung makes it difficult for babies to clear the lung of fluid, recruit lung volume, and maintain a functional residual capacity of gas in the lung at end-expiration to facilitate gas exchange. This leads to widespread atelectasis and characteristic changes on chest radiographs (low-volume lungs that have diffuse *ground-glass* opacification with *air bronchograms* visible in the lung fields).

Significant advances in the prevention and management of RDS have occurred over the last 40 years. Administration of intramuscular corticosteroids to women who are at risk of delivering preterm reduces the risk of death from and severity of respiratory disease in preterm infants.[9–11] Respiratory support—supplemental oxygen, continuous positive airway pressure (CPAP), and mechanical ventilation—was widely used from the 1980s. Exogenous surfactant therapy was a tremendous advance for preterm infants as it reduced mortality and respiratory morbidity in babies with RDS.[18–23] Improvements in knowledge and methods of invasive and noninvasive ventilation in preterm infants has have also improved their outcome.[12–17]

Pneumothorax

Pneumothoraces in preterm infants are associated with increased mortality and severity of lung disease along with other long-term morbidities. The main precipitator of pneumothoraces is RDS, and similar to RDS, the risk of pneumothorax is higher in more preterm infants, with approximately 7% of infants born at <29 weeks gestation affected.[16,17,24] Signs of pneumothorax include a marked deterioration in respiratory status with increased clinical signs of respiratory distress and increased oxygen requirements; blood gas analysis may show hypoxia, hypercapnia, and respiratory acidosis. Breath sounds may be decreased on the affected side, and there may be asymmetry of chest wall movement on examination. Diagnosis is confirmed by chest x-ray or, in emergencies, chest transillumination with a cold light source. Small pneumothoraces in a stable infant may resolve spontaneously; however, the majority of large pneumothoraces, especially those under tension with midline shift, are treated with chest drain insertion or needle aspiration with or without chest drain insertion.

Pulmonary hemorrhage

Pulmonary hemorrhage—bleeding directly into the lung parenchyma—is reported in 3%–7% of preterm infants with RDS and is associated with significant mortality and morbidity.[22,24] It is characterized by fresh blood seen coming up the trachea and into the mouth or out the endotracheal tube if the infant is receiving mechanical ventilation. The causes of pulmonary hemorrhage are poorly understood. It is thought to be associated with abnormal and rapidly changing blood flow in the vessels in the lungs over the first few days of life.[23,25] Associated factors include RDS, invasive mechanical ventilation, patent ductus arteriosus (PDA), and coagulopathy. There is a statistically significant increased incidence in preterm infants who receive prophylactic surfactant, but not in infants who receive surfactant as a rescue therapy for RDS.[26,27] There are few proven treatments for pulmonary hemorrhage. Strategies commonly used include measures to increase the mean airway pressure during mechanical ventilation (e.g., relatively higher positive end-expiratory pressure, high-frequency oscillation) and to close a PDA.

Bronchopulmonary dysplasia and chronic lung disease

Chronic respiratory insufficiency is a leading cause of death in preterm infants and is associated with poor neurodevelopmental outcome in survivors. The term

bronchopulmonary dysplasia (BPD) was originally used to describe the findings on histological examination of samples of lung tissue taken from preterm infants who had died from respiratory failure. As more preterm infants survived, the term *BPD* was applied to infants who had characteristic changes on chest x-ray and were oxygen dependent at 28 days of life. As greater numbers of infants born at earlier gestations survived, it became apparent that 28 days of life was quite a different stage of development for infants born at 24 weeks compared to infants born at 34 weeks of gestation. Chronic lung disease (CLD) of prematurity was thus diagnosed in infants who still had an oxygen requirement at 36 weeks corrected gestational age (CGA). The risk of BPD is highest in infants born extremely preterm and VLBW, with 25%–30% of VLBW infants requiring supplemental oxygen at 36 weeks CGA.[22] BPD is caused by a combination of factors and is most frequently seen, but not specific to, infants who had severe RDS requiring prolonged mechanical ventilation and with high oxygen requirements. Consequences of BPD include long-term oxygen therapy including the potential need for home therapy; feeding difficulties necessitating long-term nasogastric/gastrostomy feeding; increased energy expenditure and subsequent poor growth and nutritional deficiencies; and increased susceptibility to respiratory infections, in particular, bronchiolitis caused by respiratory syncytial virus (RSV).

Apnea of prematurity

Apnea of prematurity is an exaggeration of the periodic breathing pattern seen in newborns and is characterized by pauses in breathing (often for more than 10–20 seconds) and accompanied by episodes of bradycardia and falls in oxygen saturation. It typically affects infants born at <32 weeks gestation. Most episodes of apnea are brief; however, prolonged episodes that are associated with bradycardia and low oxygen saturations should be prevented as both factors have been associated with an increased risk of long-term neurodevelopmental problems. Treatment options include gentle tactile stimulation, nasal CPAP with or without supplemental inflating pressure, and the use of methylxanthines, caffeine or theophylline. Caffeine has been proven to lower the incidence of BPD.[28]

CARDIOVASCULAR

Blood pressure

There is little consensus on either the normal range of systemic blood pressure in preterm infants or the optimal method of treatment for infants whose blood pressure is considered low.[29,30] An ELBW infant's blood pressure generally spontaneously increases over the first 24 hours of life. A commonly used definition for *normal* blood pressure in preterm newborns is that the mean arterial pressure reading, taken from an invasive arterial catheter, should be equal to or above the gestational age in weeks. Clinicians looking after preterm infants should take into account other clinical signs of organ and tissue perfusion such as capillary refill time, urine output, and laboratory markers such as blood lactate. Infants who are determined to have low blood pressure are often treated with volume expanders (e.g., normal saline) and vasoactive medications (e.g., dopamine, dobutamine, adrenaline), and sometimes with steroids (e.g., hydrocortisone). The rates of treatment for hypotension vary widely between centers.

Patent ductus arteriosus

The ductus arteriosus is a vessel that connects the pulmonary artery and descending aorta in the fetus. In the days after birth, the ductus closes as the infant adapts to extrauterine life. If it fails to close, the PDA provides a persistent connection between the pulmonary artery and aorta. Extremely preterm infants are at greatest risk of developing a PDA. The clinical significance depends on the amount and direction of blood flow across the open duct. Over the first few days of life, when the pulmonary blood pressures decrease and systemic blood pressure increases, blood flows in a left-to-right (systemic to pulmonary) direction across the duct. Clinical signs of a PDA include a pan-systolic murmur on auscultation, bounding peripheral pulses on palpation, and a wide pulse pressure (large difference between systolic and diastolic blood pressure measurements). Diagnosis of a PDA is made on echocardiography. Concerns may arise if the left-to-right-side flow of blood causes increased pulmonary blood flow, which can result in pulmonary overload and pulmonary hypertension, and decreased systemic blood flow, leading to hypoperfusion of other organs including the brain. The majority of PDAs close spontaneously over time. However, there are treatment options available if the duct is thought to be causing significant compromise. The prostaglandin synthase inhibitors indomethacin and ibuprofen can be used to treat a known PDA or *prophylactically* to prevent PDA.[31–34] Surgical ligation of PDA, via left lateral thoracotomy, can be carried out in some preterm infants in whom the PDA is thought to be causing significant problems such as dependence on mechanical ventilation.

Congenital heart disease

Similar to infants born at term, preterm infants are at risk of congenital structural cardiac defects. Preterm infants born with defects that require surgical intervention have a significantly poorer prognosis than term infants with similar lesions due to their smaller size and technical difficulty in carrying out surgical repair. Frequently, these infants have to grow before surgical correction can be attempted, and the mortality and morbidity of preterm infants who do reach surgery is higher than term infants undergoing similar operations.

CENTRAL NERVOUS SYSTEM

Intraventricular hemorrhage

Intraventricular hemorrhage (IVH) is the most common neurological complication of preterm delivery and is associated with an increased risk of adverse long-term neurological outcome. IVH is diagnosed and monitored on cranial ultrasound carried out sequentially over the first few days of life and throughout admission to the NICU. IVH are caused by bleeding from the germinal matrix, the small network of capillaries around the caudate nucleus of the immature brain, into the surrounding ventricular system. The germinal matrix disappears by 32 weeks gestation,[2] and therefore, the infants most at risk of developing an IVH and in particular severe IVH are the most premature infants. Typically, IVH develops within the first 72 hours of birth. IVHs are traditionally graded from I to IV.[35] The term *grade I–II* IVH usually describes a small amount blood that is visible within the ventricles. *Grade III* IVH usually means that the intraventricular blood has caused ventricular dilatation, and *grade IV* means that blood is visible in the brain parenchyma, with 10%–20% of infants born before 30 weeks gestation being affected.[36] The most severe complications of IVH are typically seen in grade III–IV bleeds and include posthemorrhagic ventricular dilatation (PHVD) with subsequent hydrocephalus, which may necessitate ventricular access device or ventricular–peritoneal shunt insertion, and porencephalic cyst formation. The rate of grade III and IV IVH[35] in babies born at 501–1500 grams has been reported as 6.4%.[5] The presence of these complications, particularly if bilateral, is associated with a poorer prognosis, with a high risk of mortality and cerebral palsy and significant learning difficulties in survivors.[6,7,36] However, prognosis varies with gestational age, and grade I–II IVH is not predictive of poor outcome.

Cystic periventricular leukomalacia

Cystic periventricular leukomalacia (PVL) describes a pattern of brain injury—holes (cysts) visible in the periventricular white matter—seen on ultrasound. The cause of PVL is thought to be a combination of factors including in utero stress, decreased cerebral blood flow, hypoxia, acidosis, inflammation, and infection. The infants most at risk are the smallest and sickest of infants in the NICU. Unlike IVH, PVL typically only appears on ultrasound 3 or more weeks after the causative event. Over time, single or multiple cystic areas can develop in the periventricular lesions, cystic PVL. Similar to IVH, infants with PVL are at a significant risk of morbidity and long-term neurodevelopmental complications,[6,7,37] with extensive bilateral cystic PVL being strongly predictive of severe motor impairment.

RETINOPATHY OF PREMATURITY

Blood vessels start to proliferate in the retina of the fetus after 30–32 weeks of gestation. Infants, particularly those born before 30 weeks gestation, are at increased risk of disorganized proliferation of blood vessels after 32 weeks postmenstrual age. Unchecked, this can lead to retinal scarring, sight loss, and eventual retinal detachment, and was responsible for an epidemic of blindness in preterm survivors in the 1950s and 1960s. Extreme preterm birth and prolonged exposure to high concentrations of supplemental oxygen increase the risk of retinopathy of prematurity (ROP). However, blindness is now an unusual outcome amongst preterm survivors, thanks largely to effective treatments (laser photocoagulation and intravitreal injection of anti–vascular endothelial growth factors) that are given to infants identified following the regular and routine ophthalmological screening.

GASTROINTESTINAL TRACT

Feeding and nutrition

Like all newborn infants, preterm infants lose weight over the first few days of life. In the third trimester, the fetus gains approximately 100–150 grams per week in utero. Preterm infants have a much higher rate of energy expenditure than if they remained in the uterus; for this reason, they in general take longer than term infants to regain their birth weight. As they are growing rapidly and have high energy requirements, it is important to give preterm infants sufficient energy and nutrients to meet their needs. The optimum way to feed a newborn infant is enterally. However, preterm infants may only tolerate small volumes of feed in the first few days of life, and this volume may only increase gradually over the first week or two of life. To ensure they receive adequate fluid and nutrients, extremely preterm infants often receive parenteral nutrition (PN) while enteral feeding is established. Preterm infants are often unable to coordinate the combination of the suck and swallow reflexes, and when they can, they often tire before they take a volume of oral feeds sufficient for their needs. As a result, preterm infants are fed wholly or partially through a naso/orogastric tube until approximately 33–35 weeks corrected gestation.

Necrotizing enterocolitis

Necrotizing enterocolitis (NEC) is the most common severe gastrointestinal problem that affects preterm infants, and it significantly increases their rates of mortality and morbidity.[2,38–41] NEC is primarily a disease of prematurity; however, term infants with specific risk factors, including perinatal asphyxia, congenital cardiac disease requiring surgery, and structural gastrointestinal conditions such as Hirschsprung's disease, may be affected.[8] Reported rates of NEC among VLBW infants range from 5% to 11%, and, as with other complications of prematurity, the more immature the infant, the greater risk (14% of infants <26 weeks, decreasing to 1% of infants born at >32 weeks).[2,5,8,24,42,43]

Typically, NEC develops in the second to third week of life; however, it is not uncommon for extremely preterm

infants who develop NEC to acutely deteriorate after the first month of life after a period of relative stability. Signs associated with the onset of NEC include abdominal distension and tenderness with or without discoloration, bilious vomits or aspirates from the naso/orogastric tube, and fresh blood in the stool. Other clinical signs include those associated with sepsis such as apnea and bradycardia, tachycardia, hypotension, temperature instability, poor perfusion, and shock.

The exact cause of NEC remains unknown. However, multiple risk factors are thought to play a contributing role; these include fetal growth restriction and decreased blood supply to the GIT either in utero or postnatally. The risk of NEC is increased in preterm infants who receive formula feed, with maternal breast milk known to be of benefit in preventing the development of NEC. The disease process starts as inflammation in the bowel wall, which progresses to tissue necrosis and eventually bowel perforation. It may be localized to one area of the bowel wall but in more severe cases is generalized and extensive. Any part of the gastrointestinal tract (GIT) can be affected; however, the terminal ileum, cecum, and ascending colon are the common sites. Diagnosis is made from clinical signs and symptoms and radiological characteristic findings on plain film of the abdomen (PFA). Abnormalities on PFA include dilated bowel loops, thickening of bowel wall, and intramural air (pneumatosis intestinalis). Air may be visible in the portal venous system, and free air may be seen if perforation occurs.

Initial management of NEC is to withhold enteral feeds and commence broad-spectrum antibiotics, which provide cover against both Gram-positive and Gram-negative organisms. If bowel perforation occurs, surgical intervention should be considered.[38,44,45] One small randomized trial showed no difference in the rates of short-term outcomes among preterm infants with perforated NEC who had either primary peritoneal drainage or a laparotomy.[45] Long-term complications of NEC include poor growth and weight gain and poorer neurodevelopmental outcome.[40,41] Stricture formation, and the possibility of associated intestinal obstruction, is a risk in infants who have recovered from NEC.

Spontaneous bowel perforation

Spontaneous bowel perforation affects extremely preterm infants. Typically, it has an earlier onset than bowel perforation associated with NEC and occurs in the first week of life before the infant is established on enteral feeds. The management is similar to that of perforated NEC.

Inguinal hernia

Inguinal hernias are commonly seen in preterm infants, with a reported incidence of 9% in all infants ≤32 weeks, 11% in infants born <1500 grams, and 17% in infants born <1000 grams.[8,46] They are seen in boys much more frequently than girls and can be unilateral or bilateral. The high incidence in convalescing preterm infants is thought to be due to a combination of weak abdominal muscles and a long period of relatively high intra-abdominal pressure associated with BPD and respiratory support. There is a high risk of strangulation, and therefore, inguinal hernias should be repaired as soon as the infant is stable and suitable for anesthetic. Inguinal hernias should be monitored closely for signs of strangulation, and parents should be educated on the signs and symptoms of hernia strangulation and be aware of the need for urgent presentation to a pediatric surgical center if strangulation occurs.

Umbilical hernia

Preterm infants are more at risk than term infants for developing umbilical hernias. Similar to inguinal hernia, they are more common in extremely preterm infants and infants with BPD. Incarceration of an umbilical hernia is rare, and in general, they resolve over time during the first year of life.

INFECTION

Preterm infants are at an increased risk of sepsis compared to their term counterparts. Infants who develop early-onset sepsis (EOS, <72 hours of life) or late-onset sepsis (LOS, onset at ≥72 hours of life) have increased risk of mortality and morbidity. Group B streptococcus and coliforms such as *Escherichia coli* are the most common organisms to cause EOS, while LOS is mainly caused by organisms that are skin commensals, such as coagulase-negative staphylococcus. Indwelling devices such as central venous catheters, peripheral venous or arterial lines, endotracheal tubes, and chest drains increase the risk of infection and act as a focus for infection. They should therefore only be inserted if absolutely necessary and should be removed as soon as possible. Strict antiseptic techniques should be followed when carrying out any invasive procedure in a preterm infant, and the skin should be monitored closely for signs of breakdown.

OTHER

Hyperbilirubinemia

Unconjugated hyperbilirubinemia is extremely common in preterm infants in the first week of life and should be treated with phototherapy, as prolonged high levels of bilirubin can be neurotoxic. Threshold levels for treatment vary depending on the gestational age of the infant, with treatment being required earlier for the more premature infants. Reference graphs for treatment levels for each gestational age are available.[47]

Electrolytes

Extremely preterm infants, especially infants born at less than 27 weeks gestation, are at risk of developing life-threatening electrolyte imbalances over the first few days of life. Of particular concern is the serum potassium

level in ELBW infants, as hyperkalemia can cause disturbances of cardiac rhythm, particularly in the setting of hypocalcemia.

Anemia

A newborn infant's blood volume is approximately 80 mL/kg. Preterm infants may require transfusion for acute blood loss (e.g., due to pulmonary hemorrhage), but more commonly, they are transfused for iatrogenic anemia caused by repeated blood sampling. Typical anemia of prematurity occurs from a few weeks to months of life. It is caused by a combination of decreased red cell production and shortened red cell life span along with increased red blood cell requirements due to rapid body growth.

Preoperative assessment

JOHN GILLICK, DAWN DEACY, AND PREM PURI

INTRODUCTION

Many congenital defects that are of interest to the pediatric surgeon can now be detected before birth; thus, the preoperative assessment of the newborn with a possible congenital anomaly starts in utero. When serious malformations incompatible with postnatal life are diagnosed early enough, the family may have the option of terminating the pregnancy in some countries. It is extremely beneficial for parents if the pediatric surgeon who is likely to manage the infant postnatally is available antenatally to provide information, be involved in management decisions, and counsel the family before birth.[1] The main goal of prenatal diagnosis is to improve the prenatal care by maternal transport to an appropriate center and delivering the baby in a timing and mode that are appropriate for the specific fetal malformation. Multidisciplinary meetings in which obstetric, neonatal, and pediatric surgical expertise is present are commonplace in most large pediatric institutions. They undoubtedly improve postnatal outcome, but as always, effective communication between all disciplines is vital. Prenatal intervention for certain congenital anomalies has been reported extensively in recent years. The success of fetal surgery has varied from condition to condition; for instance, antenatal closure of myelomeningocele is associated with a lesser requirement for subsequent ventricular shunting and improved motor outcomes at 30 months.[2] However, vesicoamniotic shunting for posterior urethral valves has not proved to be the cure-all it was once hoped to be.[3] But it seems clear that fetal surgical intervention is here to stay and is likely to continue to expand its repertoire.[4,5] At present, however, almost all congenital malformations can be successfully managed after birth.

During the past two decades, there have been significant advances in modes and techniques for prenatal diagnosis. These modes include amniocentesis, amniography, fetoscopy, fetal sampling, and ultrasonography. The latter, enabling direct imaging of fetal anatomy, is a noninvasive technique, safe for both the fetus and the mother.[6] With further advances in screening techniques, and combining various antenatal screening modalities, such as the Serum, Urine and Ultrasound Screening Study (SURUSS) for Down syndrome,[7] the efficacy and safety of antenatal screening has improved. However, it is important to remember that sonography is operator dependent and the reliability of the information obtained is directly proportional to the skill and experience of the sonographer. For example, it is important to distinguish duodenal from jejunal obstruction in a fetus with polyhydramnios, because duodenal obstruction is associated with Down syndrome and requires further genetic evaluation, while jejunal obstruction does not.

The real-time sonography may yield important information on fetal malformation, fetal movement, and fetal vital functions such as breathing movements and heart rate variability. Again, this information may guide postnatal intervention.[8,9] Serial sonographic evaluations are particularly useful in following the progression or regression of any fetal disease. All this important information is an integral part of the preoperative assessment of a newborn with any kind of congenital malformation (Figures 10.1 and 10.2).

Neonates born with congenital malformations are usually in urgent need of surgery and, in addition to their surgical problem, may suffer from a multitude of medical problems. Furthermore, they are at a period when significant physiological and maturational changes, involving transition from fetal to extrauterine life, are occurring. The surgical and anesthetic intervention at this time may affect this transition by interfering with normal homeostatic controls of circulation, ventilation, temperature, fluid, and metabolic balance. To facilitate a smooth preoperative course, close cooperation among the neonatologist, pediatric surgeon, and pediatric anesthesiologist is necessary.

All neonates undergoing surgery must be carefully assessed preoperatively, giving particular attention to the following:

- History and physical examination
- Maintenance of body temperature

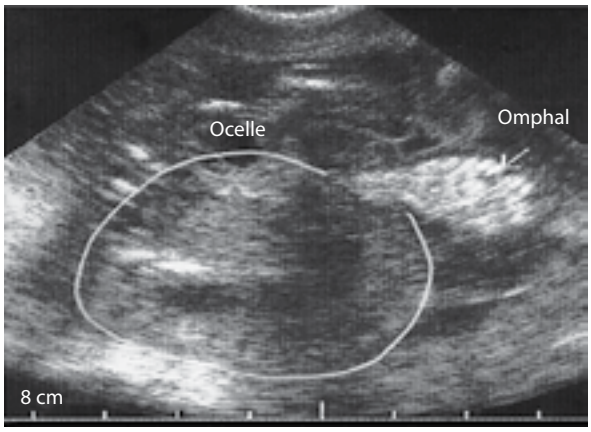

Figure 10.1 Transvaginal ultrasonogram showing a 15-week-old fetus with omphalocele (arrow). Bowel loops protrude through the abdominal wall defect.

Figure 10.2 Transvaginal ultrasonogram showing a 16-week-old fetus with diaphragmatic hernia. The dilated stomach (arrow) appears in the left hemithorax adjacent to the heart.

- Respiratory function
- Cardiovascular status
- Metabolic status
- Coagulation abnormalities
- Laboratory investigations
- Vascular access
- Fluid and electrolytes, and metabolic responses

HISTORY AND PHYSICAL EXAMINATION

The history of a newborn starts months before delivery, as many of the congenital malformations (e.g., Bochdalek hernia, omphalocele, gastroschisis, sacrococcygeal teratoma and others) nowadays are known to the pediatric surgeon prenatally. The increasing importance of antenatal pediatric surgical input in counseling parents has been recently reported.[10,11] Not only are the anatomical and structural anomalies important, but even more so are metabolic abnormalities or chromosomal aberrations, which must be diagnosed prenatally or immediately after birth.

Anticipation of a problem in the delivery room is often based on prenatal diagnosis. For example, identification of trisomy 21 in the fetus will increase the neonatologist's awareness in evaluating the infant for those abnormalities closely associated with this chromosomal defect, e.g., evaluation for duodenal atresia and congenital heart disease. Conversely, prenatal identification of specific fetal anomalies should signal the pediatrician to evaluate the infant for a chromosomal abnormality.[7]

The most important recent advance in prenatal detection of anatomical problems has been the development of fetal ultrasonography. In experienced hands, this mode of imaging can be used to detect a wide range of fetal problems and guide postnatal prognosis,[12] ranging from relatively minor abnormalities to major structural defects. However, this anatomical prenatal diagnosis is only one of the tools that aid in planning care management. An accurate and well-documented family history may increase the suspicion that an infant is at risk for an anatomical defect linked to an inherited disorder. In other cases, only the evidence of polyhydramnios should significantly increase suspicion of congenital anomalies.

Most problems are best managed expectantly by natural labor and vaginal delivery. Opinion remains divided on the benefits of elective cesarean section or preterm delivery for abdominal wall defects, with some authorities finding only limited usefulness,[13] and others suggesting that it results in an improved surgical outcome.[14] Certain malformations, however, such as conjoined twins,[15] giant omphalocele, sacrococcygeal teratoma, or large cystic hygroma, often require cesarean section for delivery.

After birth, the assessment of the degree of prematurity, which is an integral part of the physical examination, and the specific type of congenital anomaly must be identified and recorded because of the profound anesthetic and postoperative implications that are involved. The normal full-term infant has a gestational age of 37 weeks or more and a body weight greater than 2500 g. Infants born with a birth weight of less than 2500 g are defined as being of low birth weight (LBW). Babies may be of LBW because they have been born too early (preterm—earlier than 37 weeks' gestational age) or because of intrauterine abnormalities affecting growth (growth retardation). *Small-for-gestational-age* (SGA) infants are those whose birth weight is less than the 10th percentile for their age. Infants may, of course, be both growth retarded and born preterm.

The principle features of prematurity are as follows:

- A head circumference below the 50th percentile
- A thin, semitransparent skin
- Soft, malleable ears
- Absence of breast tissue

- Absence of plantar creases
- Undescended testicles with flat scrotum and, in females, relatively enlarged labia minora

The physiological and clinical characteristics of these babies are as follows:

- Apneic spells
- Bradycardia
- Hypothermia
- Sepsis
- Hyaline membrane disease
- Blindness and lung injury due to use of high levels of oxygen
- Patent ductus arteriosus

In the SGA infant, although the body weight is low, the body length and head circumference approach those of an infant of normal weight for age. These babies are older and more mature. Their clinical and physiological characteristics are as follows:

- Higher metabolic rate
- Hypoglycemia
- Thermal instability
- Polycythemia
- Increased risk of meconium aspiration syndrome (MAS)

In relation to these differences, three important observations have been reported:

1. LBW infants have a mortality 10 times that of full-sized infants.
2. More than 75% of overall perinatal mortality is related to clinical problems of LBW infants.
3. The rate of anatomical malformation in LBW infants is higher than for infants at term.[16]

MAINTENANCE OF BODY TEMPERATURE

The mean and range of temperature for newborns are lower than previously described, and most temperatures ≤ 36.3°C are, in fact, within the normal range.[17] Newborn infants, particularly premature infants, have a poor thermal stability because of a higher surface area/weight ratio, a thin layer of insulating subcutaneous fat, and a high thermoneutral temperature zone. The newborn readily loses heat by conduction, convection, radiation, and evaporation, with the major mechanism being radiation. Shivering thermogenesis is absent in the neonate, and the heat-producing mechanism is limited to nonshivering thermogenesis through the metabolism of brown fat.[18] Cold stress in these neonates leads to an increase in metabolic rate and oxygen consumption, and calories are consumed to maintain body temperature. If prolonged, this leads to depletion of the limited energy reserve and predisposes to hypothermia and increased mortality. Hypothermia can also suggest infection and should trigger diagnostic evaluation and antibiotic treatment if required.[19]

Illness in the newborn, particularly when associated with prematurity, further compounds the problems in the maintenance of body temperature. The classic example for such an illness is the newborn with omphalocele or gastroschisis. In their group of 23 neonates with gastroschisis, Muraji et al.[20] found that hypothermia (31°C–35.4°C), which was found in seven patients upon arrival at the hospital, was the most serious preoperative problem. To minimize heat losses, it is desirable that most sick neonates be nursed in incubators within a controlled temperature. These incubators are efficient for maintaining the baby's temperature but do not allow adequate access to the sick baby for active resuscitation and observation. Overhead radiant heaters, servo-controlled by a temperature probe on the baby's skin, are preferred and effective in maintaining the baby's temperature; they also provide visual and electronic monitoring and access for nursing and medical procedures. Recent studies are investigating the value of plastic coverings, hats, and heated humidified gas in maintaining euthermia.[21] In addition, hyperthermia should be avoided, because it is associated with perinatal respiratory depression and detrimental outcomes in the short-term period postdelivery.

The environmental temperature must be maintained near the appropriate thermoneutral zone for each individual patient because the increase in oxygen consumption is proportional to the gradient between the skin and the environmental temperature.[22] This is 34°C–35°C for LBW infants up to 12 days of age and 31°C–32°C at 6 weeks of age. Infants weighing 2000–3000 g have a thermoneutral zone of 31°C–34°C at birth and 29°C–31°C at 12 days. In an incubator, either the ambient temperature of the incubator can be monitored and maintained at thermoneutrality, or a servo system can be used. The latter regulates the incubator temperature according to the patient's skin temperature, which is monitored by means of a skin probe on the infant. The normal skin temperature for a full-term infant is 36.2°C, but because of many benign factors such as excessive bundling, ambient temperature may affect body temperature. Diurnal and seasonal variations in body temperature have also been described.[17] Thus, the control of the thermal environment of the newborn, and especially the ill baby with congenital malformations, is of the utmost importance to the outcome.

RESPIRATORY FUNCTION

Assessment of respiratory function is essential in all neonates undergoing surgery. The main clinical features of respiratory distress are restlessness, tachypnea, grunting, nasal flaring, sternal recession, retractions, and cyanosis. These symptoms are occasionally present in the delivery room due to anatomical abnormalities involving the airway and lungs and require the most urgent therapy.[23] Table 10.1 lists some common conditions that may be present with

Table 10.1 Approach to respiratory distress postdelivery

Condition	Prenatal and perinatal associations	Clinical features	Chest radiographic findings[a]	Initial therapy
Respiratory distress syndrome (RDS)	Prematurity, lung immaturity, asphyxia, maternal diabetes, male sex	Increasing respiratory distress after birth, tachypnea, grunting, rib retractions or nasal flaring	Diffuse reticulogranular pattern, air bronchograms	Oxygen, assisted ventilation
Air Leak Syndromes				
Pneumothorax	RDS, meconium aspiration, endotracheal resuscitation, diaphragmatic hernia, assisted ventilation	Acute onset of sternal recession, tachypnea, cyanosis, shift in apex beat position	Intrapleural air, mediastinal shift; varying degrees of lung collapse which is always symmetrical toward the hilum	Oxygen, needle aspiration, chest drain; additional tubes may be needed when large leaks from the lung tissue are present
Diaphragmatic hernia (Bochdalek)	Polyhydramnios	Sudden respiratory distress usually soon after birth, dyspnea, cyanosis, scaphoid abdomen, shift in heart sounds, decreased breaths sounds in one hemithorax (usually left)	Bowel pattern in one hemithorax, mediastinal shift with compression of the contralateral lung. Abdominal bowel gas is sparse or absent.	Nasogastric decompression; intubation and ventilation
Lung Abnormalities				
Lobar emphysema	Occasionally associated with congenital malformations of the heart and great vessels	Rapidly progressive respiratory distress with dyspnea and cyanosis, absent or diminished breath sounds over the affected side and displacement of the mediastinum	Hyperinflation of the affected side—usually left upper (increased translucency). Mediastinum may be shifted.	Thoracotomy and lobectomy required. During induction of anesthesia, the ventilator pressures must be kept as low as possible until the chest is open.
Congenital cystic adenomatoid malformation (CCAM)	Fetal hydrops, polyhydramnios, pulmonary hypoplasia, mediastinal shift, type II—associated anomalies including prune belly syndrome and pectus excavatum. 25% of infants are stillborn.	Severe respiratory distress as above, often within hours of birth	Homogeneous mass or multicystic lesion on chest x-ray, mediastinal shift. The normal location of the stomach is of help in differentiating between CCAM and diaphragmatic hernia.	Thoracotomy and lobectomy

(*Continued*)

Table 10.1 (Continued) Approach to respiratory distress postdelivery

Condition	Prenatal and perinatal associations	Clinical features	Chest radiographic findings[a]	Initial therapy
Esophageal atresia with tracheoesophageal fistula	Polyhydramnios, associated malformations (vertebral, anal, cardiac, tracheo-esophageal, renal, limb [VACTERL]), excessive nasopharyngeal saliva	Mild respiratory distress. Early chest auscultation is normal. The abdomen may show progressive distension (in the common case of atresia and fistula).	Wide, air-filled pouch in the neck or upper mediastinum. Aspiration may be noted, usually in the right upper lobe. Radioopaque nasogastric tube will be seen to stop and coiled in the blind pouch. The abdomen frequently shows hyperaeration of the intestines.	Position of the infant with head elevated 45° or prone position. Place Replogle tube in the blind proximal pouch and connect it to continuous suction. Antibiotics. Evaluate associated congenital malformations.
Airway Abnormalities				
Choanal atresia and supralaryngeal lesions	None	Cyanosis at rest, pink when crying; inability to pass catheter through nares; noisy upper airway	None	Placement or oral airway

[a] Combined chest and abdominal film is recommended in every newborn baby presenting with respiratory distress. An opaque nasogastric tube in the stomach has an important role in both diagnosis and treatment.

respiratory distress at birth. These conditions include the following: diaphragmatic hernia (Bochdalek), lobar emphysema, pneumothorax, esophageal atresia with or without tracheoesophageal fistula, congenital airway obstruction, congenital cystic adenomatoid malformation of the lung, MAS, and aspiration pneumonia. It is important to recognize that more than one condition may be present in the same patient.

If there is any clinical suspicion or sign of respiratory insufficiency, a chest x-ray should be obtained immediately after the resuscitation to determine the cause of respiratory distress. All babies with respiratory distress should have a radiopaque nasogastric tube passed and a radiograph taken that includes the chest and abdomen in order to localize the esophagus, stomach, and bowel gas, and to avoid misdiagnosis, for example, a diaphragmatic hernia that can be mistaken for a cystic adenomatoid malformation of the lung.[24] Blood gas studies are essential in the diagnosis and management of respiratory distress. Arterial pO_2 and pCO_2 indicate the state of oxygenation and ventilation, respectively. In the newborn,[25] repeated arterial blood samples may be obtained either by catheterization of an umbilical artery or by cannulation of radial, brachial, or posterior tibial arteries. An important alternative is noninvasive monitoring techniques with transcutaneous pO_2 monitors or pulse oximeters.[26] Monitoring of arterial pH is also essential in patients with respiratory distress. Acidosis in the neonate produces pulmonary arterial vasoconstriction and myocardial depression. Respiratory alkalosis causes decreased cardiac output, decreased cerebral blood flow, diminished oxyhemoglobin dissociation, and increased airway resistance with diminished pulmonary compliance.[27]

Respiratory failure is the leading cause of death in the neonate. High-frequency ventilation, use of surfactant, use of inhaled nitric oxide (iNO), and extracorporeal membrane oxygenation (ECMO) have been shown to improve survival in select neonates.[28–31] ECMO provides long-term cardiopulmonary support for patients with reversible pulmonary and/or cardiac insufficiency. It is well accepted as a standard of treatment for neonatal respiratory failure refractory to conventional techniques of pulmonary support.[29] Typically, patients considered for ECMO are 34 gestational weeks or older or weigh more than 2000 g, have intracranial hemorrhages less than grade 2, have no significant coagulopathies, and have had mechanical ventilation for fewer than 7–10 days. Our knowledge of the benefits and associated risks of neonatal ECMO continue to evolve.[32]

Improvements in other support modalities, such as iNO, have tempered the use of ECMO in recent years.[32] More recently, a respiratory strategy based on permissive hypercapnia has been implemented, but its long term benefits have yet to be confirmed.[33] This strategy focuses on avoiding volutrauma/barotraumas/oxygen toxicity while using preductal oximetry to guide therapeutic interventions. Oxygen is administered to maintain the preductal SaO_2 > 90% (pO_2 > 60 mmHg), with a corresponding pCO_2 of less than 60 mmHg and pH of more than 7.2. An important feature of this strategy is the minimal use of a muscle relaxant.

Muscle paralysis not only eliminates the infant's inherent respiratory effort but also predisposes the infant to develop tissue edema, while also accelerating lung injury.[34]

Surfactant replacement is commonly used in the clinical management of neonates with respiratory distress syndrome (RDS). It may also be effective in other forms of lung disease, such as MAS, neonatal pneumonia, the "adult" form of acute respiratory distress syndrome (ARDS), and congenital diaphragmatic hernia (CDH). It ensures that alveolar stability is promoted, atelectasis is reduced, edema formation is decreased, and the overall work of respiration is minimized.[31]

Nitric oxide (iNO) is available for treatment of persistent pulmonary hypertension of the neonate (PPHN). It decreases pulmonary vascular resistance, leading to diminished extrapulmonary shunt, and has a microselective effect, which improves ventilation/perfusion matching. Unfortunately the beneficial effects of iNO in premature infants are less clear cut, and its use in these patients has been cautioned.[30,35] In newborns with severe lung disease, high-frequency oscillatory ventilation (HFOV) is frequently used to optimize lung inflation and minimize lung injury. Further studies are needed in order to elucidate the benefits of HFOV compared to conventional ventilation in neonates, particularly those who are extremely preterm.[36]

In summary, the type of respiratory care in particular neonates will always depend upon clinical and radiological findings supported by blood gas estimations.

CARDIOVASCULAR STATUS

At birth, the circulation undergoes a rapid transition from fetal to neonatal pattern. The ductus arteriosus normally closes functionally within a few hours after birth, while anatomical closure occurs 2–3 weeks later.[37] Prior to birth, the pulmonary arterioles are relatively muscular and constricted. With the first breath, total pulmonary resistance falls rapidly because of the unkinking of the vessels with expansion of the lungs and also because of the vasodilatory effect of inspired oxygen. However, during the first few weeks of life, the muscular pulmonary arterioles retain a significant capacity for constriction, and any constricting influences such as hypoxia may result in rapid return of pulmonary hypertension.[23]

The management of neonates with congenital malformation is frequently complicated by the presence of congenital heart disease. At this time of life, recognition of heart disease is particularly difficult. There may be no murmur audible on first examination, but a loud murmur can be audible a few hours, days, or a week later.[38] A newborn undergoing surgery should have a full cardiovascular examination and a chest x-ray. The presence of cyanosis, respiratory distress, cardiac murmurs, abnormal peripheral pulses, or congestive heart failure should be recorded. If there is suspicion of a cardiac anomaly, the baby should be examined by a pediatric cardiologist. In recent years, the use of the noninvasive technique of echocardiography allows accurate anatomical diagnosis of cardiac anomalies, in many cases prenatally.[8]

METABOLIC STATUS

Acid–base balance

The buffer system, renal function, and respiratory function are the three major mechanisms responsible for the maintenance of normal acid–base balance in body fluids. Most newborn infants can adapt competently to the physiological stresses of extrauterine life and have a normal acid–base balance. However, clinical conditions such as RDS, sepsis, congenital renal disorders, and gastrointestinal disorders may result in gross acid–base disturbances in the newborn. Four basic disturbances of acid–base physiology are metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. In a newborn undergoing surgery, identification of the type of disorder, whether metabolic or respiratory, simple or mixed, is of great practical importance to permit the most suitable choice of therapy, and for it to be initiated in a timely fashion.[39] The acid–base state should be determined by arterial blood gas and pH estimation, and must be corrected by appropriate metabolic or respiratory measures prior to operation.

Hypoglycemia

The mechanisms of glucose homeostasis are not well developed in the early postnatal period; this predisposes the neonate, especially the premature neonate, to the risk of both hypoglycemia and hyperglycemia. Prenatally, the glucose requirements of the fetus are obtained almost entirely from the mother, with very little derived from fetal gluconeogenesis. Following delivery, the limited liver glycogen stores are rapidly depleted, and the blood glucose level then depends on the infant's capacity for gluconeogenesis, the adequacy of substitute stores, and energy requirements. From a glucose metabolism point of view, the neonate is considered to be in transition between the complete dependence of the fetus and the complete independence of the adult.[40] Table 10.2 identifies infants who are at risk for developing

Table 10.2 Categories of hypoglycemia

Limited glycogen stores
Prematurity
Prenatal stress
Glycogen storage disease
Hyperinsulinism
IDM (infant of diabetic mother)
Nesidioblastosis/pancreatic islet adenoma
Beckwith–Wiedemann syndrome
Erythroblastosis fetalis/exchange transfusion
Maternal drugs
Diminished glucose production
SGA
Rare inborn errors

hypoglycemia according to three mechanisms: (1) those with limited glycogen stores, (2) hyperinsulinism, and (3) diminished glucose production.[41] Premature and LBW infants (especially SGA infants) are at increased risk of both hypoglycemia and hyperglycemia due to immature postnatal metabolic and hormonal adaptation.[40,42] Surgical stress and concomitant feeding practices may further exacerbate matters. Interestingly, operative stress in neonates causes significantly less energy expenditure than comparable procedures in adult practice.[43]

Hypoglycemia is usually defined as a serum glucose level <1.6 mmol/L in the full-term neonate and <1.1 mmol/L in the LBW infant during the first 3 days of life. After 72 hours, serum glucose concentration should always be above 2.2 mmol/L.

Hypoglycemia may be asymptomatic or associated with a number of nonspecific signs such as apathy, apnea, a weak or high-pitched cry, cyanosis, hypotonia, hypothermia, tremors, and convulsions. The differential diagnosis includes other metabolic disturbances or sepsis. The possibility of hypoglycemia must be anticipated to prevent avoidable brain damage.

All neonates undergoing surgery should have an infusion of 10% glucose at a rate of 75–100 mg/kg body weight per 24 hours, and blood glucose levels should be monitored every 4–6 hours by Dextrostix estimation and/or by blood sugar determinations. Blood glucose level should be maintained above 2.5 mmol/L at all times. The symptomatic infant should be treated urgently with 50% dextrose, 1–2 mL/kg intravenously, and maintenance i.v. dextrose 10%–15% at 80–100 mL/kg per 24 hours.

Hypocalcemia

Hypocalcemia is usually defined as a serum calcium value <1.8 mmol/L. However, occasionally, the ionized fraction of the serum calcium may be low, but without a great reduction of the total serum calcium level concomitantly and with the end result of clinical hypocalcemia. This may occur in newborns undergoing exchange transfusion, or in any surgical baby receiving bicarbonate.

Hypocalcemia occurs usually during the first few days of life, with the lowest levels of serum calcium seen during the first 48 hours. The most common causes of neonatal hypocalcemia include decreased calcium stores and decreased renal phosphate excretion. The LBW infants are at greater risk, particularly if they are premature or associated with a complicated pregnancy or delivery. Hypocalcemia may be asymptomatic or associated with nonspecific signs such as jitteriness, muscle twitching, vomiting, cyanosis, and convulsions. Asymptomatic hypocalcemia can be effectively treated by a continuous infusion of 10% calcium gluconate 75 mg kg^{-1} day^{-1} and can be prevented by adding calcium gluconate to daily maintenance therapy. The symptomatic patients should be treated by slow i.v. administration of 10% calcium gluconate, 6 mL in a LBW infant and 10 mL in a full-term infant, with monitoring of heart rate to prevent too rapid an injection. Serum calcium levels should be maintained within the 2.0–2.63 mmol/L (8–10.5 mg%) range.

Hypomagnesemia

Hypomagnesemia may occur in association with hypocalcemia in SGA infants and neonates with increased intestinal losses. If there is no response to correction of calcium deficiency, a serum magnesium level should be obtained. The treatment of hypomagnesemia is by i.v. infusion of 50% magnesium sulfate 0.2 mL/kg every 4 hours until the serum magnesium level is normal (0.7–1.0 mmol/L).

Hyperbilirubinemia

Jaundice in the newborn is a common physiological problem seen in 60% of term neonates and 80% of premature infants.[44] It is the result of a combination of shortened red cell survival, with a consequent increase in bilirubin load, and an immature glucuronyl transferase enzyme system with a limited capacity for conjugating bilirubin. This results in transient physiological jaundice, which reaches a maximum at the age of 3–4 days but returns to normal levels at the end of the first week, and the bilirubin level does not exceed 170 mmol/L.

Hyperbilirubinemia in the newborn may have a pathological basis such as severe sepsis, Rh and ABO incompatibilities, and congenital hemolytic anemias. Neonatal hemolytic jaundice usually appears during the first 24 hours of life, whereas physiological jaundice, as mentioned before, reaches a peak between 2 and 5 days of life. Other causes for prolonged hyperbilirubinemia, including those often associated with surgical conditions, are as follows: biliary obstruction, hepatocellular dysfunction, and upper intestinal tract obstruction. The diagnosis of extrahepatic biliary obstruction should be done as early as possible, because early operations for biliary atresia are essential to obtain good short-term as well as long-term results.[45] The major concern in neonatal hyperbilirubinemia (high levels of unconjugated bilirubin) is the risk of kernicterus (bilirubin deposition in the brain), which can result in brain damage.

Predisposing factors for jaundice include the following: hypoalbuminemia (circulating bilirubin is bound to albumin), hypothermia, acidosis, hypoglycemia, hypoxia, caloric deprivation, and the use of drugs (e.g., gentamicin, digoxin, furosemide). When the serum bilirubin concentration approaches a level at which kernicterus is likely to occur, hyperbilirubinemia must be treated. The infant's gestational age must be taken into account, as kernicterus can occur in the absence of profound hyperbilirubinemia in premature infants. In most patients, other than those with severe hemolysis, phototherapy is a safe and effective method of treating hyperbilirubinemia. When the serum indirect bilirubin level rises early and rapidly and exceeds 340 mmol/L, hemolysis is usually the reason, and exchange transfusion is indicated.

COAGULATION ABNORMALITIES

Coagulation abnormalities in the neonate should be sought preoperatively and treated. The newborn is deficient in vitamin K, and this should be given as 1 mg prior to surgery in order to prevent hypoprothrombinemia and hemorrhagic disease of the newborn. Thus, 1 mg vitamin K should be administered by i.m. or i.v. injection to every newborn undergoing surgery. Neonates with severe sepsis, such as those with necrotizing enterocolitis, may develop disseminated intravascular coagulopathy with a secondary platelet deficiency. Such patients should be given fresh-frozen plasma, fresh blood, or platelet concentrate preoperatively.

Bleeding has been one of the major risks associated with neonatal ECMO.[46] Hemostatic adjuncts and antiplatelet agents are used sparingly and with caution while on ECMO due to the concern of severe thrombotic events and the lack of supporting evidence.[47] Heparin-bonded circuits are becoming more widely used and may assist in minimizing systemic heparinization in select patients, such as those who develop an intracerebral bleed or CDH patients needing to be repaired on ECMO.[48]

The potential for an increased rate of intraventricular hemorrhage (IVH) has also been reported in preterm neonates following iNO therapy. iNO leads to a prolonged bleeding time and an inhibition of platelet aggregation.

LABORATORY INVESTIGATIONS

A newborn undergoing surgery should have blood drawn on admission for the various investigations, including full blood count, serum sodium, potassium and chloride, urea, calcium, magnesium, glucose, bilirubin, and group and cross-match. Blood gas and pH estimation should also be obtained to assess acid–base state and the status of gas exchange. The availability of micro methods in the laboratory has minimized the amount of blood required to do the aforementioned blood tests. The coagulation status of infants who have been asphyxiated may be abnormal and should be evaluated.[49] Neonatal sepsis can result in disseminated intravascular clotting and severe thrombocytopenia. A platelet count <50,000/mm^3 in the neonate is an indication for preoperative platelet transfusion. Blood cultures should be obtained wherever there is a suspicion of sepsis.

VASCULAR ACCESS

Most newborns with surgical conditions cannot be fed in the operative and early postoperative periods. It is essential, therefore, to administer fluids in these patients by the i.v. route. With the availability of 22- to 24-gauge plastic cannulas, percutaneous cannulation of veins has become possible even in small premature infants. Scalp veins and veins of the dorsum of the hand and palmar surface of the wrist are the most common sites used for starting i.v. infusion. With the improvements of techniques and equipment, it is now rarely necessary to perform a "cut-down" in order to administer i.v. fluids.

Longer-term venous access can be obtained with fine percutaneous intravascular central catheters inserted at the bedside without general anesthesia: so-called PICC lines (peripherally inserted central venous catheters [CVCs]). Theses catheters can be successfully inserted by dedicated nursing personnel[50] and provide long-term venous access with a reduced incidence of thromboembolic complications. To minimize complications, it is important to ensure that the catheter tip resides in a central vein.[51]

Adequacy of the intravascular volume and the function of the heart can be assessed by a CVC, which can be inserted through the umbilical vein, internal jugular vein, subclavian vein, and femoral vein. Usually, catheters are placed using the Seldinger technique. This central line is often mandatory and a basic monitoring device for the anesthetist at the time of operation, and sometimes can be performed in the theatre immediately before starting the operation. It is a useful instrument for fluid resuscitation, administration of medication, and central venous pressure monitoring. The next step in the venous access hierarchy is the tunneled central line (commonly Hickman or Broviac). These are typically placed in either a neck or groin vein in neonates. PICC and tunneled central lines are relatively comparable in terms of efficacy and complications; however, if access is required for longer than 2 weeks, a tunneled central line is more suitable.[52] However, CVC lines are not free from risks. Incidence of sepsis in neonates with central lines has been reported at 28%.[53] Most catheter-related bloodstream infections respond to appropriate antibiotic treatment and/or catheter removal.[54]

Critically ill neonates will require an arterial line especially at the time of operation, either because of the surgery, when it is expected to result in significant fluid shift and hemodynamic instability, or because of significant underlying cardiopulmonary disease of the newborn. This arterial line is for monitoring the hemodynamic and biochemical status, especially throughout the operative procedure. Right radial artery percutaneous catheterization is preferred because it allows sampling of preductal blood for measurement of oxygen tension. If the neonate has already had an umbilical artery catheter, it is safer to use it strictly for the purpose of blood pressure monitoring and blood sampling and not for the administration of drugs.

A good fixation of all these venous and arterial lines is essential as these newborns have to be transported frequently, and reinsertion of these vascular lines can be very difficult.

In an emergency, temporary vascular access can also be obtained by the intraosseous route.[55]

FLUID AND ELECTROLYTES, AND METABOLIC RESPONSES

Estimation of the parental fluid and electrolyte requirements is an essential part of management of newborn

infants with surgical conditions. Inaccurate assessment of fluid requirements, especially in premature babies and LBW infants, may result in a number of serious complications.[56] Inadequate fluid intake may lead to dehydration, hypotension, poor perfusion with acidosis, hypernatremia, and cardiovascular collapse. Administration of excessive fluid may result in pulmonary edema, congestive heart failure, opening of ductal shunts, bronchopulmonary dysplasia, and cerebral IVH.

In order to plan accurate fluid and electrolyte therapy for the newborn, it is essential to understand the normal body "water" consumption and the routes through which water and solute are lost from the baby. In fetal life around 16 weeks' gestation, total body water (TBW) represents approximately 90% of total body weight, and the proportions of extracellular and intracellular water components are 65% and 25%, respectively.[57] At term, these two compartments constitute about 45% and 30%, respectively, of total body weight, indicating that (1) a shift from extracellular water to intracellular water occurs during development from fetal to neonatal life and (2) relative TBW and extracellular fluid volume both decrease with increasing gestational age.[57] SGA infants have greater TBW than appropriate for gestational-age infants.[58]

In very small premature infants, water constitutes as much as 85% of total body weight, and in the term infant, it represents 75% of body weight. The TBW decreases progressively during the first few months of life, falling to 65% of body weight at the age of 12 months, after which it remains fairly constant.[59] The extracellular and intracellular fluid volumes also change with growth. These changes are shown in Table 10.3.

The objectives of parenteral fluid therapy are to provide the following:

- Maintenance fluid requirements needed by the body to maintain vital functions
- Replacement of preexisting deficits and abnormal losses
- Basic maintenance requirement of water for growth

Maintenance fluid requirement consists of water and electrolytes that are normally lost through insensible loss, sweat, urine, and stools. The amount lost through various sources must be calculated to determine the volume of fluid to be administered. Insensible loss is the loss of water from the pulmonary system and evaporative loss from the skin. Approximately 30% of the insensible water loss occurs through the pulmonary system as moisture in the expired gas; the remainder (about 70%) is lost through the skin.[59]

Numerous factors are known to influence the magnitude of insensible water loss. These include the infant's environment (ambient humidity and ambient temperature[22]), metabolic rate,[60] respiratory rate, gestational maturity, body size, surface area, fever, and the use of radiant warmers and phototherapy.[61] In babies weighing less than 1500 g at birth, insensible loss may be up to three times greater than that estimated for term infants.[62] Faranhoff and colleagues found insensible water loss in infants weighing less than 1250 g to be 60–120 mL kg^{-1} day^{-1}.[63] Chief among the factors that affect insensible water loss are the gestational age of the infant and the relative humidity of the environment.[64] Recently, it has been reported that the application of a semipermeable polyurethane membrane (Tegaderm) to skin of extremely-low-birth-weight (ELBW) infants shortly after birth decreased postnatal fluid and electrolyte disturbances and significantly improved their outcome by reducing severity of lung disease and decreasing mortality.[65]

Respiratory water loss is approximately 5 mL/kg per 24 hours and is negligible when infants are intubated and on a ventilator. Water loss through sweat is generally negligible in the newborn except in patients with cystic fibrosis or severe congestive heart failure, or at high environmental temperature. Fecal water losses are 5–20 mL kg^{-1} day^{-1}.

RENAL FUNCTION, URINE VOLUME, AND URINE CONCENTRATION IN THE NEWBORN

The kidneys are the final pathway regulating fluid and electrolyte balance of the body. The urine volume is dependent on water intake, the quantity of solute for excretion, and the maximal concentrating and diluting abilities of the kidney. Renal function in the newborn infant varies with gestational age and should be evaluated in this context. Very preterm infants younger than 34 weeks' gestational age have reduced glomerular filtration rate (GFR) and tubular immaturity in the handling of the filtered solutes when compared to term infants. Premature infants between 34 and 37 weeks' gestational age undergo rapid maturation of renal

Table 10.3 Changes in total body water (TBW) and body compartments during development

Age	TBW (% body weight)	Extracellular fluid (% body weight)	Intracellular fluid (% body weight)
Premature	75–80	–	–
Newborn	70–75	45	35
3 months	70	35	35
1 year	60	27	40–45
Adolescence			
Male	60	20	40–45
Female	55	18	40

Table 10.4 Metabolic and electrolyte changes of the healthy newborn[a]

Variable	Phase I	Phase II	Phase III
Age	1–3 days	3–6 days	6–7 days
Intake	Low consumption of breast milk	Intake of breast milk rose progressively	Intake of breast milk stable

[a] This group of 10 male newborn babies includes 5 who were healthy and 5 who suffered degrees of fetal distress.

[b] Potassium probably gives the most sensitive indication of metabolic changes at this time of life. The day on which potassium balance first became positive varied a good deal.

[c] Balance may be slightly positive or slightly negative.

[d] Transition to positive balance. In preterm, infants all three phases can last longer and have more profound changes.

function similar to term infants with rapid establishment of glomerulotubular balance early in the postnatal period.[66] Extremely premature infants followed to school age, however, demonstrate a reduced GFR compared to term infants, presumably due to impaired postnatal nephrogenesis.[67]

The full-term newborn infant can dilute urine to osmolarities of 30–50 mmol/L and can concentrate it to 550 mmol/L by approximately 1 month of age. The solute for urinary excretion in infants varies from 10 to 20 mmol per 100 cal metabolized, which is derived from endogenous tissue catabolism and exogenous protein and electrolyte intake. In this range of renal solute load, a urine volume of 50–80 mL/100 cal would provide a urine concentration of between 125 and 400 mmol/L. If the volume of fluid administered is inadequate, urine volume falls, and concentration increases. With excess fluid administration, the opposite occurs. We aim to achieve a urine output of 2 mL/kg/hour, which will maintain a urine osmolarity of 250–290 mmol/kg (specific gravity, 1009–1012) in newborn infants. For older infants and children, hydration is adequate if the urine output is 1–2 mL/kg/hour, with an osmolarity between 280 and 300 mmol/kg.

Accurate measurements of urine flow and concentration are fundamental to the management of critically ill infants and children, especially those with surgical conditions and extensive tissue destruction or with infusion of high osmolar solutions. In these situations, it is recommended that urine volume be collected and measured accurately.

SERUM ELECTROLYTES AND METABOLIC RESPONSES IN NEONATAL SURGICAL PATIENTS

Electrolyte and metabolic responses to surgical trauma in neonates must be assessed against the background of the normal metabolic responses of an infant to extrauterine life. Table 10.4 represents a reasonable composite of some of the changes occurring in the metabolism of electrolytes, nitrogen, water, and calories in healthy newborn infants.[68] After birth, the neonate must make a transition from the assured continuous transplacental supply of glucose to a variable fat-based fuel economy. The normal infant born at term accomplishes this transition through a series of well-coordinated metabolic and hormonal adaptive changes. In premature and growth-retarded infants, there is impaired ketogenesis, in addition to imprecise neonatal insulin secretion in response to blood glucose.[42] In response to sepsis or surgical trauma, it seems that neonates divert the products of protein synthesis/breakdown from growth to tissue repair. Following surgical stress, oxygen consumption and energy expenditure in neonates return to baseline figures after 12–24 hours.[43] This is greatly different from the situation in adult surgical practice.

Table 10.5 shows fluid and electrolyte disturbances, their mechanisms, and treatment of common neonatal surgical conditions.

PREOPERATIVE MANAGEMENT OF VARIOUS SURGICAL NEONATAL CONDITIONS

Preoperative management is critical to the success of surgical intervention and the postoperative restoration of normal function. It has been observed that patients who have operations conserve sodium postoperatively.[69] In fact, this sodium concentration is usually caused by hypovolemia, which has its genesis in preoperative dehydration, because of various surgical conditions. The remedy is to provide parenteral maintenance fluid preoperatively when oral restriction of

Table 10.5 Fluid and electrolyte disturbances in common neonatal surgical conditions

Neonatal condition	Fluid and electrolyte disturbances	Mechanism	Treatment
Tracheoesophageal fistula	Mild dehydration	External loss of salivary secretions, lack of intake	Volume replacement with dextrose–saline
	Hyponatremia		
Pyloric stenosis	Dehydration, hypokalemia, hypochloremia, metabolic alkalosis	Loss of gastric secretions, hydrogen ions, potassium, and chloride	Volume replacement with dextrose–saline and potassium chloride
Pyloric atresia			
Peritonitis			
Necrotizing enterocolitis	Severe dehydration	Shift of fluids into third space, loss of sodium in stool or emesis, low blood pressure with poor peripheral perfusion	Fast volume replacement
Perforated viscus	Hyponatremia		Blood or blood products
	Metabolic acidosis, hyperkalemia, high levels of BUN		Dextrose–saline
Upper intestinal obstruction			
Duodenal atresia	Mild to severe dehydration	Loss of gastric and duodenal fluids: hydrogen ions, chloride, and bicarbonate	Volume replacement with dextrose–saline and potassium chloride
Malrotation (Ladd bands)	Hypothermia, hypochloremia, hypocalcemia		
Midgut volvulus			
Low intestinal obstruction			
Ileal atresia	Dehydration, hyponatremia, metabolic acidosis, hypokalemia	Loss of fluids into the intestine; enterocolitis	Fluid replacement by dextrose–saline, plasma, and blood as needed
Hirschsprung disease			
Imperforate anus			
Abdominal wall defects			
Omphalocele	Severe dehydration, metabolic acidosis, hyponatremia	Loss of serum from the intestinal wall in gastroschisis; aspiration of large volume of bile by nasogastric catheter; low perfusion	Urgent fluid replacement by plasma, albumin, Ringer's lactate
Gastroschisis			

fluid is required. Some patients may need fluid resuscitation preoperatively, and their extracellular fluid volume must be restored. Assessment of adequacy of the intravascular space can be done by measurement of pulse, blood pressure, capillary filling in the skin, core temperature, temperature of the skin, urine output, specific gravity, and urinary sodium level. In addition to vital signs, an accurate weight, and especially changes in weight, electrolyte levels and calcium and blood gas analyses should be obtained. Attempts should be made to correct any abnormalities encountered during this assessment.

Newborn surgical patients shift large amounts of protein and water into tissues or into potential spaces such as the peritoneal or pleural cavity. These so-called third-space losses are hard to quantify. Inadequate replacement of these losses can cause hypovolemia and shock. This is commonly seen in peritonitis (e.g., necrotizing enterocolitis, perforated viscus) and other congenital abnormalities such as gastroschisis and omphalocele. Infusion of colloid in the form of fresh-frozen plasma, 5% albumin, packed red cells, whole blood, or plasma-like product is required to maintain intravascular integrity in the face of protein and fluid losses.

Table 10.6 Electrolyte content of bodily fluids[a]

Fluid	Na^+	K^+	Cl^-	HCO_3^-
Gastric	20–80	5–30	100–140	0
Pancreatic	120–140	5–15	90–120	110
Bile	130–160	5–15	80–120	40
Small intestine	100–140	5–25	90–135	30
Ileostomy	45–135	3–15	20–115	13–100
Diarrhea	10–90	10–80	10–110	15–50
Sweat				
Normal	10–30	3–10	10–35	0
Cystic fibrosis	50–130	5–25	50–110	0

[a] Values are in mEq/L.

Enterocolitis complicating Hirschsprung disease or other intestinal obstructive lesions can cause massive losses of fluid and electrolytes and result in hypovolemia, hyponatremia, metabolic acidosis, and hypokalemia. In the presence of severe enterocolitis secondary to obstruction, with accompanying large fluid losses into the intestine, adequate preoperative fluid replacement is mandatory to ensure a reasonable outcome. Intraoperative homeostasis should be maintained through administration of appropriate volumes of isotonic crystalloid and colloid.[70] The benefits of colloid over crystalloid solutions in pediatric practice are as of yet unproven and based on results extrapolated from adult practice.

Vomiting of gastric contents as a result of gastric outlet obstruction caused by a duodenal obstruction, pyloric stenosis, intestinal bands, or malrotation results in a chronic loss of gastric contents and primary hydrogen and chloride ions, in turn resulting in hypochloremic alkalosis. Chronic hypochloremic alkalosis results in hypokalemia. In renal compensation, hydrogen ions are conserved at the expense of potassium loss. Preoperative management of patients with gastric outlet obstruction includes fluid replacement and at least potential correction of the hypochloremic alkalosis by infusion of chloride and potassium chloride (Table 10.5). This preoperative metabolic correction greatly enhances surgical outcome. Table 10.6 represents the electrolyte content of bodily fluids, which are lost by various routes and must be corrected with the appropriate balance to be replaced accurately.

Bilateral obstruction uropathy exhibits a number of important and sometimes complex abnormalities of electrolyte metabolism and acid–base regulation. Depending on the severity of a lesion, patients can have dehydration, fluid overload, hypernatremia, hyponatremia, hyperkalemia, renal tubular acidosis, and azotemia with variable degrees of renal failure. Patients with water and salt-losing nephropathy need additional salt and water supplements. Patients with defective dilutional capacity and renal failure require fluid restriction. Patients with renal tubular acidosis require bicarbonate supplementation with or without potassium exchange resins.

FLUID MANAGEMENT PROGRAM

Based on a consideration of the sources of water loss, an average parenteral fluid design for an infant receiving no oral feeding should provide about 40 mL of water per 100 cal metabolized for insensible loss and 50–80 mL/100 cal for urine, with about 5 mL/100 cal for stool water, resulting in a total volume of 100–125 mL/100 cal for the maintenance fluid losses under baseline conditions per 24 hours. LBW infants will require considerably more fluid because of an increasing insensible loss. Neonates weighing less than 1000 g may need 160 mL/kg per 24 hours, and those over 1000 g may require 110–130 mL/kg per 24 hours. With premature infants, a fluid intake >170 mL/kg per 24 hours is associated with an increased risk of congestive cardiac failure, patent ductus arteriosus, and necrotizing enterocolitis.

Serial measurements of body weight are a useful guide to TBW in infants. Fluctuations over a 24-hour period are primarily related to loss or gain of fluid, 1 g body weight being approximately equal to 1 mL water. Errors will occur if changes in clothing, dressings, and tubes are not accounted for and if scales are not regularly calibrated.

The assessment of hydration status in every newborn surgical patient is essential for the infant's outcome. This can best be obtained by changes in body weight, measurement of urine flow rate, concentration of urine, hematocrit, and total serum protein. Estimation of serum electrolytes, urea, sugar, and serum osmolarity gives a good indication of the hydration status.

Anesthesia

NICHOLAS EUSTACE AND KAY O'BRIEN

Over the past 80 years or so, provision of anesthesia for the neonate requiring surgery has developed from being a relatively haphazard affair to achieving the status of a recognized subspecialty. The improved survival rates seen following surgery, where even the smallest and sickest infants are concerned, have been due in no small part to advances in anesthetic management. Equally important has been an increased appreciation of the need for an efficient smooth-working team. The success of neonatal surgery depends on maximum cooperation between surgeon, anesthetist, neonatologist, and nursing and paramedical personnel. It is appropriate, therefore, that everyone involved in the care of neonates, whether working inside or outside the operating theater, should be familiar with the basic techniques used in maintaining a favorable physiologic milieu in the face of surgical intrusion, while at the same time ensuring adequate anesthesia. This chapter will consider the preoperative evaluation and preparation of the surgical neonate, anesthetic equipment, choice of anesthetic agent and technique (with reference to the pharmacology of the newborn), induction of anesthesia and endotracheal intubation, maintenance and reversal of anesthesia, perioperative monitoring and fluid therapy, the anesthetic implications of congenital anomalies, and finally, specific considerations for the premature infant undergoing surgery.

PREOPERATIVE PREPARATION AND EVALUATION

Much neonatal surgery is performed on an emergency basis. However, operation is rarely so urgent as not to allow for adequate evaluation and stabilization beforehand. The cornerstone of preoperative anesthetic management is a detailed knowledge of the infant's history combined with a thorough physical examination. Consideration must also be given to the specific surgical procedure to be undertaken and its implications in terms of potential blood loss, monitoring requirements, and postoperative care.

History

Although many neonates requiring surgery are aged only a few hours, considerable information that is useful as regards anesthetic management will have been accumulated by the time of the anesthetist's visit. This information should be obtained from the parent(s) (if available) and medical and nursing colleagues. Of profound importance is an accurate estimation of gestational age, as prematurity has profound implications for the anesthetist (see later). Trends in blood pressure and heart rate, including bradycardias, body weight, fluid intake and output, laboratory measurements, x-ray appearances, and the extent of any respiratory support required or apneas, are very helpful in planning anesthetic technique, anticipating problems, and planning postoperative management. A knowledge of recent and current drug therapy is essential.

Physical examination

The anesthetist should make a brief appraisal of the infant's overall condition and follow this with a careful assessment of individual body systems. The neonate's weight should be recorded accurately. Overhydration or hypovolemia can be detected by assessment of skin turgor, the anterior fontanelle, and liver size. Peripheral vasoconstriction may indicate either hypovolemia or acidosis. Signs of respiratory failure include nasal flaring, tachypnea, chest wall recession, grunting respiration, or apneic spells. Airway anatomy should be carefully assessed in order that potential difficulties with endotracheal intubation can be anticipated. One should look for *other* associated congenital anomalies in the surgical neonate. This is particularly so when examining the cardiovascular system (e.g., one-third of infants with esophageal atresia also have some form of congenital heart disease). Accurate preoperative neurological assessment is mandatory in infants presenting for anesthesia for neurosurgery. Finally, potential difficult intravenous (i.v.) access and the possible need for central access for inotropes or postoperative total parenteral nutrition should be evaluated.

Laboratory investigations

Minimum laboratory data required include full blood count, blood urea and serum electrolytes, blood glucose and calcium, and coagulation profile. Arterial blood gas analysis for pH, oxygen and carbon dioxide partial pressure (pO_2 and pCO_2), and bicarbonate levels is also frequently indicated. The preoperative hemoglobin level should be at least 12 g/dL—if lower, consideration should be given to transfusion with packed red blood cells prior to anesthesia and surgery. Any dehydration, hypovolemia, hypoglycemia, hypocalcemia, or hypokalemia or hyperkalemia should be corrected. pH, pO_2, pCO_2, and body temperature should be normalized.

Premedication

Sedative premedication is not used in neonates. However many pediatric anesthetists consider it advisable to administer an anticholinergic drug in order to reduce secretions and to protect against bradycardia. Atropine is the most widely used drug, usually in a dose of 0.02 mg/kg by i.v. injection immediately prior to induction of anesthesia.

Prior to transfer to the operating theater, the anesthetist should confirm the following:

- The infant has been fasting for at least 2 hours (but not for much longer unless an i.v. fluid infusion is in progress)
- Blood has been crossmatched (if indicated)
- Vitamin K, 0.5–1 mg intramuscular (i.m.), has been administered (to allow for possible deficiency in vitamin K–dependent clotting factors)
- The stomach has been decompressed (especially in cases of intestinal obstruction)

Estimated blood volume, allowable blood loss, and maintenance fluid requirements should be calculated. Where it is anticipated that multiple vascular access routes will be required (e.g., for central venous pressure or direct arterial pressure monitoring), it may be advisable to establish these in the intensive care unit (ICU) before transfer to the operating theater, as it is usually easier to maintain an infant's body temperature in the ICU environment. Importantly, overall fitness must be assessed in light of the urgency of surgery. This may require consultation between anesthetist, surgeon, and other interested personnel. If transfer to the operating theater is considered to be unacceptably hazardous, for example, in the case of some extremely ill and low-birth-weight infants, it may be advantageous to undertake surgery in the ICU itself.[1,2]

TRANSFER TO THE OPERATING THEATER

The time during which the neonate is transferred to the operating theater is one that is not without hazard. Risks are minimized if he or she is accompanied by experienced medical and nursing personnel and if the theater is close at hand. Transfer should be in either an incubator or an isolette with overhead heater to reduce heat loss. Any treatment in progress (e.g., i.v. fluid or drug infusion, respiratory support) should be continued by the use of battery-operated infusion pumps and portable respiratory equipment. Monitoring should not be interrupted during this hazardous phase.

OPERATING THEATER AND ANESTHETIC EQUIPMENT

The prime objectives of neonatal anesthesia are the provision of sleep, analgesia, life support, intensive surveillance, and appropriate operating conditions for the infant requiring surgery. In order for these to be achieved, it is imperative that both operating theater environmental conditions and anesthetic equipment be appropriate. It has been shown that maximum heat loss occurs between the time of arrival of the neonate in theater and the skin incision. Measures should be taken to minimize the risk and extent of this occurrence. Before the infant arrives, the theater, which should be draught free, should be warmed to a temperature of 24°C or 25°C. Once the baby is removed from the incubator or isolette, he or she should be placed on a water or air mattress that has been heated to 40°C and kept covered as much as possible—plastic drapes and blankets are particularly useful in this regard. If an overhead radiant heater is available, it should be set to maintain skin temperature at 36°C. Other measures that assist in maintaining body temperature during this critical period include warming and humidifying inspired anesthetic gases and warming i.v. and skin preparation fluids.

Breathing systems

An appropriate anesthetic circuit for use in infants needs to be light, have minimal resistance and dead space, allow for warming and humidifying of inspired gases, and be adaptable to spontaneous, assisted, or controlled ventilation. While the T-piece system originally designed by Philip Ayre[3] and later modified by Rees[4] is still used by some, circle systems are currently more popular. Connectors and tubes should also offer minimal flow resistance and dead space.

Most endotracheal tubes used during neonatal anesthesia are manufactured out of polyvinyl chloride. A knowledge of the probable diameter and length of tube appropriate for any given infant is essential but must always be confirmed clinically. The optimal diameter is the largest that will pass easily through the glottis and subglottic region and will produce a slight leak when positive pressure is applied. A convenient guideline for length of orotracheal tube from gum to midtrachea is 7 cm for an infant weighing 1 kg, with an additional centimeter for each kilogram increase in weight.[5] Use of an endotracheal tube of too large a diameter may result in tracheal wall damage, while excess length leads to endobronchial intubation. Newer cuffed pediatric endotracheal tubes are available, (Microcuff by Kimberly-Clarke),

but the recommended size must be used.[6] Once satisfactory positioning has been confirmed visually and by auscultation of both lungs, the tube should be taped securely to prevent accidental extubation. Consideration should be given to secondary fixation to the forehead to prevent rotational movement. Face masks are generally used for only brief periods in neonates but should provide a good fit and have a low dead space. Oral airways are not generally necessary except in cases of choanal atresia but have the advantage of splinting the endotracheal tube and preventing lateral movement.

The incidence of airway complications associated with the laryngeal mask airway (LMA) in infants is high.[7] However, the device can occasionally prove useful, especially when endotracheal intubation is difficult.[8,9]

Laryngoscopes

Because of the anatomical peculiarities of the infant's airway, most anesthetists prefer to use a laryngoscope with a straight blade, lifting the epiglottis forward from behind to facilitate intubation. The Miller number 0 and 1 blades are suitable in most cases. A recent advance has been the development of videolaryngoscopes such as the GlideScope, for use in neonates.[10]

Ventilators

Most infants and children can be ventilated using standard adult ventilators provided the ventilator is of low internal compliance and equipped with pediatric breathing tubes. The ventilator should be capable of delivering small tidal volumes and rapid respiratory rates, and have an adjustable inspiratory flow rate and inspiratory–expiratory ratio so that peak airway pressure is kept as low as possible.[11] Pressure-controlled ventilation is widely used in order to minimize the risk of pulmonary barotrauma. A suitable temperature-controlled humidifier should be incorporated in the inspiratory side of the ventilator circuit. The ability to deliver air–oxygen mixtures through the ventilator or anesthetic circuit should be available.

Monitoring equipment

A complete range of monitoring equipment suitable for infant use is required.

CHOICE OF ANESTHETIC AGENT AND TECHNIQUE

Neonates perceive pain, while even babies born at 28 weeks gestation mount a substantial and potentially harmful response to surgically induced stress.[12] Thus, few would argue with the contention that adequate anesthesia must be provided for all infants undergoing surgery. The anesthetic agents employed are similar to those used for older children and adults. However, the responses of the neonate to these potent drugs differ in a number of respects from those seen in older patients. An understanding of these differences is essential for the safe conduct of neonatal anesthesia and also influences choice of anesthetic agent and technique. The issue of possible neurotoxic effects of general anesthetics on the developing brain has received considerable attention in recent years, and there seems little doubt that until there is more clarity as regards the actual degree of risk, any surgery that is truly elective should be deferred until the infant attains an as-yet undefined older age.[13,14]

Inhalation agents

Inhalation induction of anesthesia with either air or nitrous oxide, oxygen, and a volatile agent remains popular. Provided that respiration is not depressed, both induction of and emergence from anesthesia are rapid in infants. The reasons for this are multiple but include the relatively higher cardiac output, greater alveolar ventilation, smaller functional residual capacity, and larger proportion of vessel-rich tissues relative to body mass seen in the newborn infant.[15,16] All potent inhalation agents lead to a dose-related depression of spontaneous respiration.[17] This is particularly important in the neonate, in whom the ventilatory response to hypoxia is one of hypoventilation. An additional consideration is that the minimal alveolar concentration (MAC) of inhaled agents required to prevent reflex responses to surgical stimulation varies with age.

HALOTHANE

Halothane was, for many years, the most widely used volatile anesthetic for inhalation induction in infants and young children. This is largely because it is usually associated with a smooth induction without irritant effects on the airway. It has been superseded in patients of all ages by agents that offer greater hemodynamic stability to the extent that it is currently unavailable in many parts of the world.

ISOFLURANE

Despite its lower blood gas solubility coefficient, inhalation induction with isoflurane is generally not as rapid or as smooth as with halothane. Indeed, this agent has been shown to be associated with a significant incidence of hypoxic episodes during inhalation induction of anesthesia in older children. Sedative premedication and use of a high inspired isoflurane concentration from the outset[18] both reduce the incidence of these adverse occurrences but are relatively contraindicated in the surgical neonate. Isoflurane has been shown to maintain systolic arterial pressure in the normal range even in preterm neonates and, unlike halothane, does not sensitize the myocardium to the effects of circulating catecholamines. It has considerable potentiating effects on nondepolarizing muscle relaxants, so that lower doses of the latter can be used. Metabolic degradation of the agent is minimal and recovery rapid. In summary, isoflurane is an excellent agent for maintenance of anesthesia but has limited use for inhalation induction.

ENFLURANE

This agent is rarely used in neonatal and pediatric anesthesia because its irritant effects render it relatively unsatisfactory for inhalation induction.

DESFLURANE

Airway irritant effects also render desflurane unsuitable for inhalation induction in pediatric practice. However, recovery times in infants are shorter than those following other volatile anesthetics. The agent has been recommended for maintenance of anesthesia in the ex-premature infant prone to apnea and ventilatory depression.[19]

SEVOFLURANE

Sevoflurane has replaced halothane for the induction of anesthesia in neonates and children. It lacks the airway irritation associated with other newer inhalation agents and provides cardiovascular stability. Induction time is similar to halothane.[20] Infants undergoing inguinal herniotomy with sevoflurane have a slower recovery than those with desflurane but no difference in postoperative respiratory events.[21] Higher concentrations of sevoflurane, commonly used for induction of anesthesia, can be associated with epileptiform electroencephalogram (EEG) changes.[22] In older children, the agent is associated with emergence delirium.[23]

NITROUS OXIDE

This gas does not provide adequate anesthesia when used alone with oxygen. It is most often employed as a carrier that supplements potent volatile anesthetics, thereby reducing the concentration required and minimizing cardiovascular depressant effects. Animal work indicated that it might induce pulmonary vasoconstriction, with resultant increased right-to-left shunting in the newborn, but this does not appear to be so.[24] It does cause moderate respiratory and cardiovascular depression. One limitation to the use of nitrous oxide in neonatal anesthesia is the fact that it is many times more soluble in blood than is nitrogen. As a result, the inhalation and subsequent diffusion of the gas cause an increase in the volume of compliant spaces. It follows that the agent should not be used in infants with congenital diaphragmatic hernia, lobar emphysema, or bowel obstruction.

Intravenous agents

THIOPENTONE

Despite the fact that it was introduced to anesthetic practice over 70 years ago and that many supposedly superior agents have since been developed, many still consider this drug to be the preferred agent for i.v. induction in infants. The induction dose $[ED]_{50}$ (effective dose, 3.4 mg/kg) is lower in neonates less than 14 days of age than in older infants.

PROPOFOL

Propofol is a highly lipophilic short-acting anesthetic agent. It has a rapid onset and short duration of action. It is currently unlicensed for use in neonates in many countries. Despite this, it is increasingly used for the induction of anesthesia in the newborn. The clearance of propofol in neonates is slower than in older pediatric patients to the extent that they are at risk of longer recovery.[25] A randomized study in infants found it to be more effective at facilitating intubation than a morphine, atropine, and succinylcholine combination.[26] It has been used successfully in the management of pyloric stenosis.[27]

KETAMINE

This agent is associated with greater cardiovascular stability than many other anesthetic drugs.[28] However, its metabolism is considerably delayed in infants below 1 year of age. It has the advantages of having a profound analgesic effect and of being capable of being given by i.m. injection.

Neuromuscular blocking agents

SUCCINYLCHOLINE

Succinylcholine has the advantage of having both a rapid onset (30 seconds) and short duration of action. Relatively higher doses (2 mg/kg) of this drug are required to produce full relaxation in infants than in adults (1 mg/kg). This is because of the neonate's larger extracellular fluid space, throughout which the drug is distributed. Succinylcholine is metabolized by plasma pseudocholinesterase. Although plasma levels of this enzyme are low in the first 6 months of life, activity is adequate to metabolize the drug, and recovery occurs after a similar time to that seen in adults (approximately 4 minutes).

Because of the number of side effects, including bradycardia, hyperkalemia, and triggering of malignant hyperpyrexia reactions associated with this agent, it has been suggested that its use in young infants should be reevaluated. However, it remains widely used in neonates.[29]

Nondepolarizing muscle relaxants

For many years, it was generally agreed that newborn infants exhibited an increased sensitivity to these agents, but recent studies have demonstrated that full relaxation demands doses similar to those used in adults. A lower plasma concentration is required (presumably because of immaturity of the neuromuscular junction), but this is produced in any event by distribution of injected drug throughout the relatively larger extracellular fluid compartment. Alterations in plasma protein binding may also play a role in determining dose requirements, which are much more variable than in adults. It follows that careful titration of dose against response is advisable and that these drugs should be administered slowly to neonates. Use of a peripheral nerve stimulator as a guide to degree of relaxation is strongly recommended.[30]

ATRACURIUM AND VECURONIUM

These two agents were introduced because their duration of action was intermediate between that of succinylcholine and

older nondepolarizing muscle relaxants such as pancuronium and because they offered increased cardiovascular stability. In addition, atracurium is attractive in that its metabolism is independent of hepatic and renal function, although it is dependent on pH and temperature. Recommended initial doses are 0.3–0.5 mg/kg for atracurium and 0.05–0.1 mg/kg for vecuronium. Because of their pharmacokinetic profiles, both drugs are suitable for use by continuous i.v. infusion, although atracurium infusion requirements show marked individual variation.

Nightingale found the duration of effect of atracurium to be longer in infants less than 3 days of age.[31] Other studies have shown the dose–response curves of this agent to be parallel in infants, older children, and adults, and in fact demonstrate recovery times to be shorter in infants.[32] Histamine release, an occasional problem with the drug in adults, is rarely seen in pediatric practice.

Vecuronium, on the other hand, has been found to have a longer recovery time in infants compared to older children and adults and should be regarded as a long-acting muscle relaxant in this age group.[33]

MIVACURIUM

Mivacurium is a short-acting nondepolarizing neuromuscular agent that is rapidly hydrolyzed by plasma pseudocholinesterase. The time course of block produced by the drug is more rapid in younger pediatric patients.[34] Satisfactory intubating conditions are not achieved as quickly as with succinylcholine, but serious side effects occur less frequently.

ROCURONIUM AND SUGAMMADEX

Rocuronium is a member of the aminosteroid family of neuromuscular blocking drugs similar to vecuronium. It has the advantage of providing a rapid onset of action similar to that of suxamethonium without the side effects associated with it. Its duration of action is similar to vecuronium. The recommended doses to provide optimal intubation conditions are 0.3–1 mg/kg.[35] It is felt that the duration of action of rocuronium in neonates is longer than in older children.[36]

Sugammadex is a selective muscle relaxant binding agent that was designed to specifically reverse the effects of aminosteroid muscle relaxants. It encapsulates rocuronium, forming a tightly bound complex that prevents the muscle relaxant from acting at the receptors. Doses prescribed are 2–4 mg/kg when reversing rocuronium-induced muscle relaxation.[37] Data for neonates is currently unavailable.

ANALGESIA

There is no doubt whatsoever that neonates perceive and respond to pain. Effective management of intraoperative and postoperative pain is required to minimize acute physiological and behavioral distress and may also improve acute and long-term outcomes.[38] Opioids, most commonly morphine, remain the gold standard in treating severe postoperative pain in neonates and infants despite concerns about adverse effects, such as respiratory depression. Care must be taken as the neonate has decreased opioid requirements compared to older children.[39] The reasons for this include immaturity of hepatic enzyme systems leading to impaired conjugation and glucuronide excretion and the greater permeability of the infant blood–brain barrier to these drugs.

It follows that where narcotics are administered to neonates intraoperatively, dosage regimens should be modified so that patient safety is not compromised. Morphine (0.05–0.1 mg/kg) and fentanyl (0.005–0.02 mg/kg) given intravenously are the two most widely used drugs, with the latter being particularly well tolerated hemodynamically. Intraoperative infusions of ultra-short-acting opioids have been used successfully, but there are limited specific data to guide remifentanil dosing in neonates.

Intravenous morphine remains popular for provision of postoperative analgesia in ventilated infants and those nursed in high-dependency areas. Morphine administration protocols vary and include continuous infusions, intermittent bolus doses, and nurse-controlled analgesia (NCA). Continuous infusion rates of 0.01–0.03 mg/kg per hour are common, but the lowest effective dose must always be used. NCA is delivered via the same type of pump as patient-controlled analgesia (PCA) with a prescribed bolus and dose interval. Occasionally, background infusions are utilized, but they may increase the risk of respiratory depression in nonventilated patients.[40] Respiratory monitoring should be continued for 24 hours after the last dose of opioid. The situation with regard to other infants is more difficult. It should be recognized that while failure to treat discomfort or pain effectively may have significant long-term effects, overaggressive treatment has its own morbidity.

The use of combined analgesic regimens, leading to adequate analgesia with lower doses of opioids and reduced side effects, has shown some promise. Opioid sparing has been demonstrated in some studies with paracetamol.[41] Nonsteroidal anti-inflammatory drugs are not widely used for analgesia in infants.[42] Currently, there is little evidence to support the use of newer opioids, e.g., tramadol, as an adjunctive therapy.[43] Codeine was used in the past for mild to moderate pain, but its use has been largely discontinued due to risks of respiratory depression, and its use is no longer recommended.

Paracetamol has become commonly used to treat mild to moderate pain. Its pharmacokinetic profile has been well documented following administration via both the rectal and i.v. routes.[44,45] Due to the risk of accidental overdosage, dosage schedules should be frequently reviewed.

Regional anesthesia

It should not be forgotten that local or regional anesthetic techniques (e.g., epidural block, intrathecal block, peripheral nerve block, transversus abdominis plane [TAP] block, wound infiltration, etc.) may be used as alternative methods of providing analgesia for infants during and after surgery. These methods may be particularly valuable, especially in

the high-risk ex-premature infant.[46,47] The availability of ultrasound has provided a useful adjunct in identification of anatomical structures, thereby enabling better placement of local anesthetic.[48]

Induction of anesthesia and endotracheal intubation

Most pediatric anesthetists advocate that infants should have anesthesia induced and a muscle relaxant administered prior to attempts at endotracheal intubation. Induction technique depends on (1) the age, size, and physical status of the infant; (2) the relative hazard of regurgitation; and (3) the personal preference of the anesthetist. In most instances, i.v. induction followed by administration of a muscle relaxant is satisfactory. Inhalation induction is an acceptable alternative. In either case, i.v. access should be established beforehand, and the induction itself should be preceded by a short period of preoxygenation.

Intubation is best accomplished with the infant's head extended at the atlanto-occipital joint. The laryngoscope blade is inserted into the right side of the mouth, displacing the tongue to the left. As the blade is advanced the epiglottis, comes into view. In the neonate, this structure is long and floppy, and it should be displaced anteriorly from behind to aid visualization of the larynx. If difficulty is encountered, the little finger of the left hand can be used to press gently on the larynx to improve visualization. The use of an atraumatic but rigid bougie can also be extremely valuable in these cases. Once intubation has been achieved, one should carefully auscultate both lungs to check for equal air entry, and the endotracheal tube should be securely fixed.

If it is considered at the time of induction of anesthesia that postoperative mechanical ventilation will be required, the tube should be inserted by the nasal rather than the oral route. It is difficult to manipulate Magill's forceps in the mouth of a small infant, but flexing the neck usually facilitates passage of nasotracheal tubes.

MAINTENANCE OF ANESTHESIA

Because of the vulnerability of the infant's respiratory system, spontaneous respiration is not used for long periods in the anesthetized neonate. Mechanical ventilation helps ensure adequate gas exchange and also leaves the hands of the anesthetist free to perform other tasks. Suitable ventilators have already been discussed and, depending on the particular machine available, may be set in either pressure or volume control modes, with a ventilatory rate of 30–40 per minute with an inspiratory time of approximately 0.6 second. With the latter, a delivered tidal volume of approximately 8–10 mL/kg is appropriate. Inspired gases should be warmed and humidified to prevent damage to the mucosal lining of the respiratory tract and to minimize heat loss. Manual ventilation allows rapid detection of airway obstruction or disconnection, and is particularly useful during thoracic surgery.

The most widely used agents for maintenance of anesthesia in the neonatal population are isoflurane and sevoflurane, usually combined with 50% oxygen with air, along with a small dose of relaxant.

Consideration should be given to using the lowest inspired concentration of oxygen where possible.

REVERSAL AND EXTUBATION

If a volatile agent has been used for maintenance of anesthesia, it should be discontinued shortly prior to the end of surgery. Once surgery has been completed, residual muscle relaxation is reversed by either neostigmine (0.06 mg/kg) or edrophonium (1 mg/kg) combined with either atropine (0.02–0.03 mg/kg) or glycopyrrolate (0.01 mg/kg). Sugammadex may also be used if rocuronium was the muscle relaxant used during surgery. Controlled ventilation is continued with 100% oxygen or with oxygen in air until spontaneous respiration has returned. Suctioning through the endotracheal tube is carried out if secretions are obviously present. The nostrils should be gently suctioned as a routine. The infant should not be extubated until fully awake and breathing adequately. In most cases, reversal of neuromuscular blockade and resumption of spontaneous respiration occur rapidly. Care is taken to correct hypothermia, acidosis, or hypoglycemia.

MONITORING

The clinical condition of the anesthetized neonate can deteriorate more rapidly and with less warning than that of patients in any other age group. It follows that careful and continuous monitoring is essential. While no piece of machinery will adequately replace the careful anesthetist, there are a number of devices available that provide helpful information that cannot be gleaned by clinical means alone. The monitoring employed in any particular case depends upon the physical status of the infant and the surgical procedure to be undertaken.

The following should be positioned prior to induction (and, indeed, regarded as the minimum equipment required for monitoring anesthetized neonates):

- Electrocardiogram (ECG)
- Blood pressure cuff
- Core temperature probe
- Pulse oximeter probes (preductal and postductal)
- End-tidal carbon dioxide monitor

Most neonates undergoing anesthesia and surgery require additional monitoring. The various options available will be discussed in relation to the particular body system being monitored.

Respiration

Chest wall movement should be observed continuously if at all possible. When mechanical ventilation is employed,

airway pressure and minute volume alarms are mandatory. Oxygenation and adequacy of gas exchange are monitored continuously by pulse oximetry and breath-by-breath end-tidal anesthetic agent and carbon dioxide measurement. Serial arterial blood gas analysis is mandatory in critically ill infants undergoing major surgery.

Cardiovascular function

Blood pressure monitoring is essential because of the reduced cardiovascular reserve of the neonate and the risk of hypotension if high concentrations of inhaled anesthetics are used. Automated oscillotonometry is employed in most instances, but concern has been expressed about the accuracy of the devices used when blood pressure is low. The cuff should be of appropriate width (approximately 4 cm).

If either the infant's physical status or the type of surgery to be performed necessitates continuous monitoring of blood pressure, an arterial line is inserted in a suitable vessel, the cannula being connected to a pressure transducer by narrow-bore tubing.

Central venous pressure monitoring is useful in infants with congenital heart disease, and also if significant blood loss (and replacement) is anticipated. The right internal jugular vein is usually the simplest to cannulate. Ultrasound is increasingly used to guide placement of central lines in neonates.

Fluid balance

The goal of intraoperative fluid management is to sustain homeostasis by providing the appropriate amount of parenteral fluid to maintain adequate intravascular volume, cardiac output, and, ultimately, oxygen delivery to tissues at a time when normal physiological functions are altered by surgical stress and anesthetic agents.[48] Maintenance fluid requirements vary considerably within the neonatal period itself but may be taken as being approximately 4 mL/kg per hour for infants older than 5 days of age. Assuming there is no preoperative fluid deficit, an i.v. infusion set at the usual maintenance rate should be commenced prior to induction of anesthesia. The composition of the administered fluid will vary according to the maturity of the baby and preoperative electrolyte and glucose levels. Because of the problems associated with hyperglycemic states in infancy and hyponatremia, care should be taken with the use of 10% dextrose infusions.[49] It is important to take into account the volume of drug diluents administered during anesthesia and surgery when calculating fluid balance.

Blood and fluid loss can be extensive and very difficult to measure during neonatal surgery. The former is best estimated by the use of small volume suction traps, by weighing small numbers of surgical swabs before they dry out, and by serial hemoglobin measurements. During lengthy surgery, serum electrolytes and blood glucose should be measured at regular intervals. Urine output may be monitored by the use of bladder catheterization. Estimated third-space loss may be replaced by continuous administration of lactated Ringer's solution at 3–5 mL/kg per hour.

Volume replacement should be undertaken when blood loss is expected to exceed 5%–10% of circulating blood volume using either 5% albumen or an isotonic crystalloid. Because of the high hematocrit at birth, red-cell replacement is seldom required during most routine neonatal surgical procedures. When required, the blood used should be as fresh as possible. Adequacy of volume replacement can be assessed by monitoring of blood pressure, heart rate, central venous pressure, acidosis on arterial blood samples, and urine output.

ANESTHESIA FOR SPECIFIC SURGICAL CONDITIONS

Esophageal atresia

Once a diagnosis of esophageal atresia (with or without fistula) has been made, the blind upper pouch should be continuously aspirated using a Replogle or similar tube. In general, operation may be safely delayed pending improvement of any aspiration pneumonia that has developed.[50]

Because of the high incidence of associated congenital heart disease, preoperative cardiology assessment, including echocardiography, is essential. Prethoracotomy bronchoscopy is practiced in some centers and may influence subsequent management.[51] Anesthesia is similar to that for other neonatal procedures, but special care must be taken with positioning of the endotracheal tube, the tip of which should be located above the carina but below any fistula present. Surgical retraction during the operation may compromise either respiratory or cardiac function, so that close monitoring is essential. Extubation may occasionally be possible at the end of the procedure.

Congenital diaphragmatic hernia

This condition was formerly regarded as one of the great emergencies of pediatric surgical practice, but it is now agreed that operation should be postponed until adequate gas exchange has been obtained and the infant is hemodynamically stable.[52]

Positive-pressure ventilation using bag and mask should be avoided prior to endotracheal intubation, as expansion of the viscera contained within the hernia will cause further lung compression. Nitrous oxide should be avoided for the same reason. A reasonable anesthetic technique includes controlled ventilation with fentanyl 0.01–0.02 mg/kg, intermediate-acting muscle relaxant, and 100% oxygen or oxygen in air as required. Great caution should be exercised in the use of volatile anesthetic agents. Airway pressures should be kept as low as possible. Should advanced ventilatory techniques such as high-frequency oscillation or nitric oxide be required in order to achieve preoperative stabilization, these may be safely continued during surgery.[53]

Most infants will require mechanical ventilation, sedation and muscle relaxation, and the management of pulmonary hypertension in the postoperative period.

Intestinal obstruction

The various forms of neonatal intestinal obstruction account for approximately 35% of all surgical procedures in the newborn. The major anesthetic problems are those of fluid and electrolyte imbalance (which must be corrected preoperatively), abdominal distension (causing respiratory embarrassment), and the risk of regurgitation and aspiration of gastric contents into the lungs. Following decompression of the stomach, a rapid-sequence induction incorporating preoxygenation, thiopentone or propofol, and succinylcholine with gentle cricoid pressure is advised. Anesthesia is then continued in the usual way.

Exomphalos and gastroschisis

Exomphalos is associated with other midline defects, especially cardiac anomalies, so that preoperative echocardiography is required. This is not true of neonates with gastroschisis. Anesthetic concerns include heat and fluid loss from the exposed bowel and the fact that closure of the abdominal wall defect may push the diaphragm cephalad, thus compromising respiratory function. Special care must be taken to keep heat loss to a minimum. Fluid requirements are much greater than in normal neonates. To maintain plasma oncotic pressure, at least 25% of fluid intake should be given as a colloid. Often, gastroschisis is closed following staged procedures using a silastic silo. The extent of respiratory compromise can assist the anesthetist in advising the surgeon on whether or not primary closure is feasible. A proportion of infants, especially after repair of gastroschisis, require postoperative mechanical ventilation. Increasingly, neonates born with a large exomphalos have the defect closed in stages over a prolonged period, requiring a tracheostomy and long-term ventilation.

Congenital lobar emphysema

This condition may cause severe respiratory distress in the neonatal period. Induction of anesthesia for lobectomy should be as smooth as possible—struggling may trap large amounts of air in the affected lobe during violent inspiratory efforts.[54] Nitrous oxide can also increase the volume of trapped air considerably and is contraindicated. Great care should be taken with controlled ventilation because of the risk of pneumothorax.

Myelomeningocele

If the defect is large, heat and fluid loss during surgery can pose problems and should be monitored as closely as possible. Surgery is carried out with the infant in the prone position, and the chest and pelvis should be supported with pads so that the abdomen remains free from external pressure. Precautions should be taken to limit the patient's exposure to latex in theater. Postoperatively, the neonate should be monitored for apnea and increasing intracranial pressure.

SPECIAL CONSIDERATIONS FOR THE PREMATURE INFANT

Congenital defects occur more commonly in preterm infants, so that surgery is frequently required. Organs and enzyme systems are very immature, and meticulous attention to detail during anesthetic and surgical management is imperative if survival rates are to be high. The large body surface area and lack of subcutaneous fat make maintenance of body temperature even more difficult than in term infants, so that a high neutral thermal environment is essential. Respiratory fatigue occurs very easily and may be exacerbated by residual lung damage following mechanical ventilation, persistent fetal circulation, and oxygen dependency. The response to exogenous vitamin K is less satisfactory than in term infants, and there is an increased risk of bleeding. In addition, anemia is common because of reduced erythropoiesis, a short erythrocyte life span, and iatrogenic causes such as frequent blood sampling. Fluid and electrolyte management can be difficult—insensitive losses are high and hypoglycemia and hypocalcemia occur easily, while renal function and the ability of the cardiovascular system to tolerate fluid loads are reduced.

Premature infants with a history of idopathic apneic episodes preoperatively are more prone than other infants to develop life-threatening apnea during recovery from anesthesia. It is recommended that infants born prematurely who undergo anesthesia and surgery while less than 60 postconceptual weeks of age should have respiratory monitoring for at least 12 hours postoperatively in order to prevent apnea-related complications.[55]

Postoperative management of the surgical neonate

SUZANNE CROWE

INTRODUCTION

As each year passes, there are advances in the perioperative management of critically ill newborns who require surgery. Developments in surgical techniques and equipment available have facilitated challenging surgical repairs in smaller infants.[1,2] This has been coupled with new anesthesia modalities, in particular with regard to regional anesthesia, and rapidly metabolized medications such as desflurane and remifentanil.[3–5] Increased operative intervention in preterm and low-birth-weight infants has increased the demand for postoperative high-dependency and intensive care.[6] Alternative respiratory and cardiovascular support in the form of extracorporeal life support, inhaled nitric oxide (NO), and high-frequency oscillation have expanded the potential to support these severely compromised infants.

Differences in physiology and pharmacology in the preterm and term neonate have a direct impact on their capacity to adapt to surgical intervention and to recover in the postoperative period. Pulmonary vascular resistance (PVR) is elevated in the first 10 days of life, which increases the potential to develop right-to-left shunt through the ductus arteriosus. This response occurs particularly in response to hypoxia or metabolic acidosis. There are distinct differences in the coagulation system as plasma levels and activities are low at the time of birth and then increase in the first few months of life. Total body water is higher in the newborn, especially the premature infant, and glomerular filtration rate (GFR) is low in the first few days of life. Thermoregulation mechanisms are poorly developed and require support. The newborn increases cardiac output by increasing heart rate because stroke volume is relatively fixed due to the thin-walled myocardium at birth. The usual stress response to surgery through hormone release and metabolic modulation is altered in the newborn, which has implications for cardiovascular monitoring, support, and sedation and analgesia. This chapter focuses on the physiological features of the surgical neonate in the postoperative period.

RESPIRATORY MANAGEMENT

Neonates have little functional respiratory reserve, which means they have a limited capacity to compensate for changes in respiratory demand. All other systems have a direct impact on respiratory function: cardiac, renal, neurological, immunological, and hematological. Changes that occur in these systems quickly alter respiratory demand and function, which the sick newborn infant may struggle to compensate for. Respiratory muscle fatigue occurs rapidly, due to reduced lung compliance, relative immaturity of the bronchioles and alveoli, and a compliant chest wall. Combined with the neonatal immature respiratory center, apnea develops early when the infant becomes ill. Major abdominal or thoracic surgical procedures that adversely affect the mechanics of the respiratory system make the neonate vulnerable to respiratory failure in the postoperative period. Particular abnormalities such as gastroschisis and congenital diaphragmatic hernia repair cause an increase in intra-abdominal pressure, with upward displacement of the diaphragm and a reduction in lung compliance. Normal tidal ventilation is just above the closing volume for the neonate, so that a reduction in tidal volumes due to abdominal splinting may lead to collapse of alveoli and loss of surface area available for gas exchange. Atelectasis leads to hypoxemia, hypercarbia, and respiratory acidosis. As the pulmonary vasculature bed remains sensitive to changes in pH, the resistance of the pulmonary circulation increases in response to respiratory acidosis, compromising the function of the right side of the heart. To prevent this physiological deterioration, neonates benefit from postoperative respiratory support.[7] The more complex the surgery, with longer duration and requirement for blood transfusion, the more likely that the infant will require a period of ventilation. This is especially the case in premature infants and those with other congenital anomalies. Advances in regional anesthesia have allowed earlier separation from ventilation as the placement of effective

local anesthetic blocks reduces the use of opiates in the early postoperative period.

VENTILATORY SUPPORT

Positive-pressure ventilation

Modern ventilators in the neonatal intensive care unit (NICU) and pediatric intensive care unit (PICU) have been designed to meet the needs of children recovering from major surgery. Oxygen and air are mixed from a pipeline supply at 50 psi. Microprocessors control the inspiratory and expiratory valves, and the gas is humidified and warmed before being delivered to the patient. The expiratory valves control the level of positive end-expiratory pressure (PEEP) applied to each cycle of respiration. Various modes of ventilation are available, ranging from complete mandatory ventilation to synchronized support ventilation and spontaneous pressure support. The range of modes allow the infant to be weaned gently from breathing support, with less lung damage than was previously associated with ventilation in children.[8]

The surgical neonate is generally commenced on time-cycled pressure-limited ventilation. A preselected pressure is set, defined as the peak inspiratory pressure (PIP), and is chosen to deliver an adequate tidal volume, taking into account the compliance of the lung and the airway resistance. In uncomplicated postoperative ventilation, PIP is usually 15–20 cm H_2O. This pressure may need to be increased significantly if there is reduced lung compliance due to pulmonary edema or increased airway resistance due to decreased thoracic compliance. The airway pressure at the end of expiration (normally zero during spontaneous respiration) may need to be increased to 5–10 cm H_2O to prevent alveolar collapse at the end of each breath. The rate of the inflations delivered by the ventilator is related to the need to excrete carbon dioxide and is usually 28–36 breaths per minute (bpm).

Patient-triggered ventilation and synchronized ventilation

Synchronized patient-triggered ventilation has many advantages in the neonate. It reduces the requirement for sedation and neuromuscular medications as the infant coordinates his/her breathing with pressure assist. Neuromuscular medications can have a prolonged duration of effect due to immature drug metabolism and renal excretion. The ventilator uses an inspiratory flow-generated trigger, which senses the commencement of inspiration and provides a set-pressure or set-volume assist. The sensitivity of the trigger may be varied by the operator, to allow earlier opening of the inspiratory valve and initiation of respiratory effort. This can either be triggered in the pressure or volume control modes as pressure support ventilation (PSV) or synchronous intermittent mandatory ventilation (SIMV), or be completely independent of the machine in the continuous positive airway pressure (CPAP) mode. Patient-generated triggering maintains muscle function during ventilation and facilitates weaning and separation from the ventilator. Different modes of ventilation have been compared in neonates with respiratory failure, most commonly in lung disease of prematurity.[9,10] There is some evidence from these randomized controlled trials (RCTs) that synchronized modes of patient-triggered ventilation may reduce air leak and reduce the duration of ventilation required.[11,12] The terminology and most common modes of ventilatory support are summarized in Table 12.1.

High-frequency oscillatory ventilation

Increased understanding of the importance of limiting peak pressures when inflating the lungs has led to the widespread use of high-frequency oscillatory ventilation (HFOV).[13,14] This mode of ventilation recruits alveoli to participate in gas exchange, keeping the lung open with a constant distending pressure. This is sometimes referred to as the "open lung" approach. Excretion of carbon dioxide is managed by adjustments to the frequency and magnitude of oscillation, and oxygenation is achieved by adjusting the mean airway pressure and the inspired content of oxygen.[15] Recruitment and stabilization of lung volumes is both pressure and time dependent.[16] In 1996, the prospective randomized trial of high frequency oscillatory ventilation versus conventional ventilation (PROVO) trial used a clearly defined lung recruitment protocol with all patients receiving surfactant and demonstrated a reduction in hospital length of stay and the incidence of chronic lung disease.[17] Commencing HFOV early rather than after lung damage has been sustained appears to improve outcome, especially in premature infants.[14,17] Some relevant features of HFOV and high-frequency jet ventilation (HFJV) are summarized in Table 12.2.

Lung-protective ventilation

The intervention of tracheal intubation and ventilation generally aims to restore blood gas analysis to within normal limits for oxygen, carbon dioxide exchange, and pH. However, achieving blood gas values within the normal range comes at a cost due to adverse consequences of PPV. High inflation pressures used to reduce carbon dioxide can result in ventilator-associated lung injury.[18] This may impact on both the lung parenchyma and the vasculature. Animal models of ventilator-induced lung injury demonstrate pulmonary edema, hyaline membrane formation, and pulmonary epithelial cell injury, which can be produced with lung inflation pressures of just 30 cm H_2O. Limiting the pressure within the lung and accepting relative hypercarbia has become known as lung-protective ventilation and is used especially in the context of premature lungs and dysplastic lungs.[19] There is also increasing evidence that hypocarbia may be injurious to the developing neonatal brain, as

Table 12.1 Commonly used forms of positive-pressure ventilation and terminology

Terminology	Descriptor	Comments
Volume ventilation or volume control ventilation	Preset TV. Patient cannot trigger the ventilator. Tidal volume is constant, while PIP may vary.	Most commonly used mode in adults and older children. Also effective in smaller children with minimal ETT leaks.
Pressure ventilation or pressure control ventilation	Preset pressure. Patient cannot trigger the ventilator. PIP is constant, but tidal volume may vary.	Commonly used in neonates. Increasing use in adults to prevent ventilator-induced lung injury in patients with ARDS.
Continuous positive airway pressure (CPAP)	Spontaneous breathing mode with no mechanically delivered breaths and positive end-expiratory pressure. High gas flow delivered by a demand valve.	First introduced to treat preterm infants with lung disease of prematurity. Now commonly used as a pre-extubation mode of respiratory support.
Assist-control ventilation	Minimum rate and TV (or pressure) set. Patient may trigger inspiration at a more rapid rate.	Common form of weaning from mechanical ventilation.
Assisted ventilation	All breaths are patient triggered at the ventilator's set volume or pressure.	Most commonly used as *pressure support* ventilation.
Mandatory ventilation, intermittent mandatory ventilation (IMV), or synchronized intermittent mandatory ventilation (SIMV)	Machine-generated breath that is triggered, limited, and cycled by the ventilator.	Not commonly used.
High-frequency positive-pressure ventilation (HFPPV)	Positive pressure delivered at rates >60/min by a conventional ventilator.	Commonly used in neonates with severe hypoxic respiratory failure.
Noninvasive ventilation (NIV), commonly known as bilevel positive airway pressure (BiPAP)	Positive pressure delivered by either nasal or face mask. Commonly used as a bilevel device with preselected inspiratory airway pressure (IPAP) and expiratory airway pressure (EPAP).	Increasingly used in patients with less severe lung disease and in premature infants. Avoids the need for intubation and risk of ventilator-associated pneumonia (VAP).
Neurally adjusted ventilator assist (NAVA)	Positive pressure initiated by detection of electrical activity in the diaphragm. May be delivered via endotracheal tube or noninvasive mask.	Comfortable weaning mode, which improves synchrony with the ventilator and allows reduction in sedation.

Note: ARDS: acute respiratory distress syndrome; TV: tidal volume.

Table 12.2 Characteristics of high-frequency ventilators

	HFOV	HFJV
Rate	180–900/min	100–600/min
VT	At high rates (>10 Hz), minimal TV. TV increases as rates decreases.	TV 2–5 mL/kg
Expiration	Active	Passive
Gas movement	Diffusion	Diffusion plus bulk flow
Indications	Used in lung disease associated with low lung compliance (MAS, IRDS) as part of an open lung strategy. Also has been extensively used in CDH.	IRDS, MAS, and bronchopleural fistula

Note: Hz: cycles per second; IRDS: infant respiratory distress syndrome; MAS: meconium aspiration syndrome; VT: tidal volume.

it impairs blood flow within the brain. Hyperventilation as a strategy to close the ductus arteriosus is no longer carried out as a result of these concerns. Earlier application of surfactant and nasal CPAP in the neonates has improved the outcome in premature infants with moderately severe forms of respiratory distress syndrome (RDS).[20,21]

Setting ventilator parameters

The choice of ventilation mode in each newborn is dependent on the condition of the infant on arrival in the PICU/NICU, and the expected course for any known pathology, e.g., giant exomphalos or tracheoesophageal fistula. The objective is to maintain gas exchange within a physiological range (PaO_2 8–12 kPa, PCO_2 5–6.5 kPa), using the lowest inspired concentration of oxygen and airway pressures compatible with that aim. This is straightforward when the lungs are normal but may require advanced ventilatory strategies in the presence of congenital or acquired abnormalities of the thorax and/or abdomen. An infant with normal lung compliance and airway resistance placed on a preset pressure ventilator would require a PIP of 10–20 cm H_2O, a rate of 25–35 bpm, a FiO_2 of 0.21–0.35, and a PEEP of 3–5 cm H_2O. Within an hour of commencement, a chest radiograph should be carried out to ensure optimum lung field expansion, and blood gas analysis performed to ensure hyperventilation is avoided.

Respiratory monitoring

Blood gas monitoring: Monitoring of respiratory function in the postoperative period requires measurement of gas exchange. The most reliable and accurate method is to measure PaO_2, $PaCO_2$, and pH from an arterial sample. The most common sites for invasive monitoring are the umbilical artery in newborns and radial or dorsalis pedis arteries in older infants. Samples drawn from the right radial artery in the newborn will measure preductal values, whereas the other sites will be postductal. On some occasions, the left subclavian artery is beside the origin of the duct and will therefore measure similarly to the right radial. Automated blood gas machines now require less than 0.2 mL of blood for analysis, which reduces the need for blood transfusions due to frequent sampling in the sick neonate. Capillary blood from a well-perfused area of skin is used to provide samples for blood gas analysis, particularly if there is no direct arterial access.

Noninvasive oxygenation and CO_2 monitoring: Pulse oximetry measures arterial saturation and heart rate on a beat-to-beat basis in a reliable and accurate fashion. The absolute values do not correlate well with measured values at arterial saturations less than 70% and in low cardiac output states where there is peripheral hypoperfusion. Careful sensor placement is important as the probe is sensitive to light artifact. It is a useful monitor in the critical care and operating theatre environment as it rapidly reflects response to intervention such as suctioning and changes in ventilation. Due to the shape of the oxygen dissociation curve, high PaO_2 levels (>95 mm Hg, 12.6 kPa) will not be accurately reflected by saturation measurements. Transcutaneous probes for both oxygen and carbon dioxide are also used, especially in premature infants. Both probes heat the skin to 41°C–44°C, augmenting cutaneous blood flow. Indirect monitors of gas exchange should be confirmed occasionally using an arterial sample. Greater accuracy is obtained by careful maintenance of the probes and care in calibration and application to the skin. Due to the risk of skin damage from the heating element, the probe site must be rotated every 4–6 hours. End-tidal CO_2 monitoring or capnography uses infrared measurement of CO_2 and provides a continuous indirect assessment of the CO_2 with each expired breath. It is a standard monitor available in most critical care units. In the presence of lung disease, the difference between the end-tidal CO_2 measurement and the PCO_2 in blood increases, and the validity of end-tidal CO_2 as a monitor declines. Because the connector is still quite cumbersome, it increases the dead space volume and may make spontaneous respiration more difficult in smaller patients.

CARE OF THE INTUBATED PATIENT IN THE PICU

Endotracheal tube (ETT) size and positioning: Newborns are commonly managed with nasotracheal tubes rather than oral tubes unless there is a congenital abnormality of or injury to the nasal area that precludes use. Nasal ETTs provide greater patient comfort and security, require less sedation to tolerate, and allow better oral care. The tube may be securely fastened to the face and nose, reducing the possibility of accidental extubation. In older children, oral tubes are satisfactory for brief periods of ventilation, but nasal tubes are frequently preferred. The ETT size is selected on the basis of weight and age (Table 12.3). In terms of length, the tip of the ETT should be between the heads of the clavicles on a plain radiograph of the chest. If a tube tip is lower than this, it may enter the right main bronchus, causing right upper lobe collapse and/or left lung collapse. This can be a cause of substantial and avoidable morbidity. A plain film of the chest should be obtained after endotracheal intubation or repositioning of the ETT to verify correct position. The proximal end of the ETT should protrude sufficiently far from the nose so that the tube connector does not compress the external nares and result in a pressure-related erosion of the skin or cartilage.

Table 12.3 Endotracheal tube size selection

Age	Endotracheal tube diameter (mm)
Preterm	2.0–2.5
Term newborn	3.0–3.5
1 month	3.5
1–6 months	3.5–4.0
1 year	4.5

Cuffed low-pressure ETTs are being used increasingly in infants, as they facilitate easier management of leak around the ETT and may reduce the incidence of ventilator-associated pneumonia, as secretions do not pass freely around the ETT and into the bronchial tree. When using an uncuffed ETT, a large leak can make ventilation extremely difficult. This is especially relevant in the postoperative period when high-pressure ventilation may initially be required. Very small tubes such as the 2.5 and 3.0 are prone to blocking with retained secretions, and routine suctioning is key in maintaining the patency and efficiency of the ETT. Suctioning may be hazardous, particularly in small infants and the premature infant, leading to hypoxia and bradycardia even when carried out with meticulous care. Suction support with preoxygenation is a feature offered on ventilators, which provides assistance in managing this complication.

Endotracheal suctioning may be used to perform a modified bronchoalveolar lavage and extract samples of alveolar secretions to be examined microbiologically. Information gained about organisms cultured may direct further treatment if infection is suspected clinically.

All ventilators combine ventilation with humidification. Humidification is important in the management of the infant's temperature and in prevention of ventilator-associated pneumonia. Loose secretions are easier to suction out of the bronchial tree; thick dry secretions risk being retained to cause plugging and atelectasis. The goal of the humidifier is to deliver fully saturated gases at a temperature of 37°C to the ETT. When infants wean from ventilation and extubate, they may continue to need supplemental oxygen and/or noninvasive ventilation—these support modalities require humidification also.

MANAGEMENT OF THE NEWBORN WITH HYPOXIC RESPIRATORY FAILURE

Neonates may present shortly after delivery with hypoxic respiratory failure. Cardiac causes must be excluded quickly. The most common cause is persistent pulmonary hypertension of the newborn (PPHN). PPHN may develop rapidly if the reactive pulmonary vascular bed is exposed to acidosis or hypoxia. This may occur in the context of meconium aspiration, airway obstruction, or sepsis. Support of the hypoxic newborn requires neonatal or pediatric intensive care admission, with commencement of HFOV.[22] Inotropic infusions are frequently needed to provide an adequate perfusion pressure as the right side of the heart struggles to pump against the high resistance of the pulmonary bed. If the right ventricle begins to fail, the left ventricular function becomes impaired, and extreme systemic hypotension and organ hypoperfusion may follow.

Nitric oxide

Inhaled NO is generally employed with HFOV in the management of these critically unwell infants.[23] NO induces relaxation of the muscular endothelium in the pulmonary vessels, which may reverse the pulmonary hypertension. When administered by the inhaled route, NO diffuses rapidly from the alveolus into the endothelial cell and the vascular smooth muscle, where it stimulates guanylate cyclase to produce cyclic guanosine monophosphate (cGMP). A series of RCTs have shown that inhaled NO improves oxygenation and reduces the need for extracorporeal membrane oxygenation (ECMO) in term neonates with PPHN.[24–26] Although the response may be dramatic, not all infants respond. Infants with right-to-left shunt without extensive parenchymal lung disease generally respond better. If there is extensive lung disease secondary to meconium aspiration or hypoplasia, reversal may not occur to the same extent.

Two phosphodiesterase inhibitors, dipyridamole and sildenafil, have been successfully used to treat the rebound pulmonary hypertension associated with the withdrawal of inhaled NO.[27] Sildenafil by continuous infusion has also been shown to be effective in infants with PPHN who have not been responsive to inhaled NO.[28] Both inhibitors may be used in combination for severe hypoxia, e.g., infants with congenital diaphragmatic hernia.

Surfactant replacement therapy

An important advance in neonatal medicine was the synthesis and introduction of surfactant replacement therapy for the treatment of lung disease of prematurity. It is administered prophylactically in patients at risk for or with established lung disease of prematurity.[29] When combined with lung-protective ventilation, it reduces the incidence of air leak and mortality.[30,31] Natural surfactant may contain additional proteins that have anti-inflammatory properties. It has been trialed in other diagnostic groups but without the same positive results. Human studies have shown that the use of surfactant replacement therapy in infants with meconium aspiration is associated with decreased need for ECMO.[32]

WEANING FROM VENTILATION

Reducing reliance on ventilatory support as quickly as possible is key to the avoidance of complications of ventilation. Cessation of medications that interfere with respiratory muscle function, i.e., muscle relaxants and, to a lesser extent, opiates, is vital in maintaining the function of the diaphragm and intercostal muscles. Gradual reduction in ventilator support may be achieved in a number of different ways, but they generally incorporate a reduction in pressure support to each breath and a reduction in the number of mandatory breaths delivered by the ventilator. As the strength and efficiency of spontaneous ventilation increases, the patient is moved to a completely spontaneous mode in the form of pressure support (PS)/CPAP. When the pressure support approaches physiological level, i.e., 5–7 cm H_2O, and the PEEP required is 3–5 cm H_2O, in <40% oxygen, extubation may be considered. However, the overall

condition of the patient must be included in this decision. If using a cuffed ETT, the cuff is deflated, and the presence of a leak around the ETT is verified. More recently, neurally adjusted ventilation assist (NAVA) is employed as a weaning mode of ventilation. It allows the patient to be awake and comfortable when triggering assisted breaths, as the electrical activity of the diaphragm is sensed early in the respiratory cycle and assistance is delivered proportional to the activity of the diaphragm. This allows the infant to vary the size and frequency of each breath while being assisted.

POSTOPERATIVE SEDATION AND ANALGESIA

It is now widely understood and accepted that neonates require sedation and analgesia to facilitate safe and humane surgical management. Effective pain relief reduces the hormonal stress response to surgery and reduces hypertension and intraventricular hemorrhage in the preterm infant.[33] Analgesia improves glucose homeostasis, reduces airway pressures, and reduces circulating endogenous catecholamines.[34] The most common opiates used in neonatal critical care are fentanyl, morphine, and remifentanil.[35] Benzodiazepines are used as an adjunct, to produce sedation, usually in the form of midazolam or lorazepam. A summary of agents employed is in Table 12.4. The proliferation of catheter-based regional anesthetic techniques in recent years has reduced the requirement for opiate analgesia.[36] Local anesthetic blocks are sited in the operating room using ultrasound guidance and are continued using continuous infusion of levobupivicaine through indwelling catheters.

HEMODYNAMIC SUPPORT IN THE NEWBORN

Cardiac output is a the product of heart rate times the stroke volume, with increase in output dependent on the ability to increase heart rate or vary stroke volume. Stroke volume is influenced by venous return (preload), impedance (afterload) to left or right ventricular output, and contractility of the myocardial muscle. The newborn myocardium is relatively immature, with little capacity to increase stroke volume. Therefore, cardiac output is largely dependent on heart rate. Compensation for falling stroke volume occurs by increasing heart rate. Blood pressure does not reflect compensation through heart rate increase and vasoconstriction, so that decompensation appears to occur suddenly, with hypotension as a late sign. Cardiac output may be estimated from the clinical parameters of heart rate, blood pressure, urine output, and skin/core temperature gradient. These parameters are combined with blood gas analysis to examine the base deficit, serum lactate, and mixed venous saturation if the blood sample is taken from a central venous line. Measurement of central venous pressure (CVP) allows optimization of right atrial filling pressure and preload.

Central venous access may be established through the internal jugular, subclavian, or femoral vein in the neonate. Ultrasonography is now part of standard practice to guide placement of central access, which is technically challenging in very small infants. The cannulation of the

Table 12.4 Commonly used agents for anesthesia and analgesia in newborns

Drug	Classification	Comments	Commonly used dosages
Morphine	Narcotic	Good analgesic effect with sedation. Cumulative effect in newborns. Withdrawal effects with sustained usage.	20–30 μg kg^{-1} $hour^{-1}$ in ventilated patients
Fentanyl	Short-acting narcotic	Potent, short-acting narcotic. Commonly used for procedural sedation in ventilated patients.	1–2 μg kg^{1} $hour^{-1}$ as a stat dose; 0.5–2 μg kg^{-1} $hour^{-1}$ as an infusion
Midazolam	Short-acting benzodiazepine	Used as sedation either as a stat dose or by continuous infusion.	1–4 μg kg^{-1} min^{-1} by continuous iv infusion; stat dose 0.1–0.2 mg/kg
Lorazepam	Benzodiazepine	More prolonged effect than midazolam. Potent anticonvulsant.	For seizures, 0.05 mg/kg iv
Ketamine	Dissociative anesthetic agent. Can be given by im or iv injection.	Good analgesic properties. Used for procedural sedation/anesthesia. Sympathomimetic effect increases blood pressure.	Stat dose for induction of anesthesia 1–2 mg/kg iv
Acetaminophen	COX inhibitor. Available as oral or rectal preparation.	Useful for mild procedural pain and as an antipyretic.	10–15 mg/kg per dose
Sucrose	Stimulates endogenous opioids	Useful for procedural analgesia.	2 mL po for term infants

Note: im: intramuscular; iv: intravenous; po: oral.

radial, posterior tibial, dorsalis pedis, or femoral artery with a 22- or 24-gauge cannula facilitates direct arterial pressure measurement and access for sampling for blood gas analysis, and electrolyte and acid/base measurement. Umbilical venous and arterial lines may be sited shortly after delivery of the infant and may be used for a short time. They can cause renal or gut ischemia if not positioned correctly.

Management of the infant with clinical signs of shock is focused on increasing preload by volume expansion with 1–20 mL/kg crystalloid or colloid boluses, followed by reassessment of the clinical picture. Further fluid boluses are frequently necessary. If increasing preload does not improve systemic perfusion, vasoactive medications may be required to support organ perfusion.

VASOACTIVE MEDICATION THERAPY IN NEONATES

Vasoactive medications produce vasodilation or vasoconstriction. Some medications also produce an increase in contractility due to direct action on the cardiac myocyte. By altering tissue oxygen delivery, heart rate, filling pressures, afterload, and contractility, these medications affect myocardial work and increase oxygen consumption. Figure 12.1 illustrates the effects of fluid administration and inotropes on the neonatal cardiac output. An ideal agent would have a balanced effect, increasing contractility and decreasing afterload, with minimal heart rate change. This medication currently does not exist, so combinations of drugs are used to maximize systemic perfusion and reduce side effects. There are a limited number of studies looking at inotropes and their effects in the neonate, with most concentrating on the infant post–cardiac surgery.[37,38]

The available vasoactive medications and their effects are summarized in Table 12.5. Generally, a beta or alpha receptor agonist such as noradrenaline or adrenaline is combined with a phosphodiesterase inhibitor such as milrinone or enoximone.[39–41] Vasopressin is a potent medication, which produces vasoconstriction independent of the beta and alpha receptors, and is used in inotrope-resistant shock, e.g., gram-negative sepsis.[42] Vasodilators in the form of sodium nitroprusside are occasionally used to reduce systemic vascular resistance (afterload). Steroids are used in inotrope-resistant shock, producing an increased perfusion pressure secondary to the effects of aldosterone.[43,44]

Fluid management and renal function

Maintenance of normal fluid and electrolyte homeostasis is challenging in the neonate as the kidneys are functionally immature. GFR is lower in the preterm infant than the term neonate, with the term neonate capable of producing dilute urine (30–50 mOsm/L), retaining adequate sodium with normal sodium intake. The kidney in the preterm infant is inefficient at conserving sodium and yet is relatively insensitive to the effects of circulating antidiuretic hormone (ADH). This reduces the capacity of the infant to produce a concentrated urine if necessary, e.g., in dehydration. The newborn has a higher proportion of extracellular water,

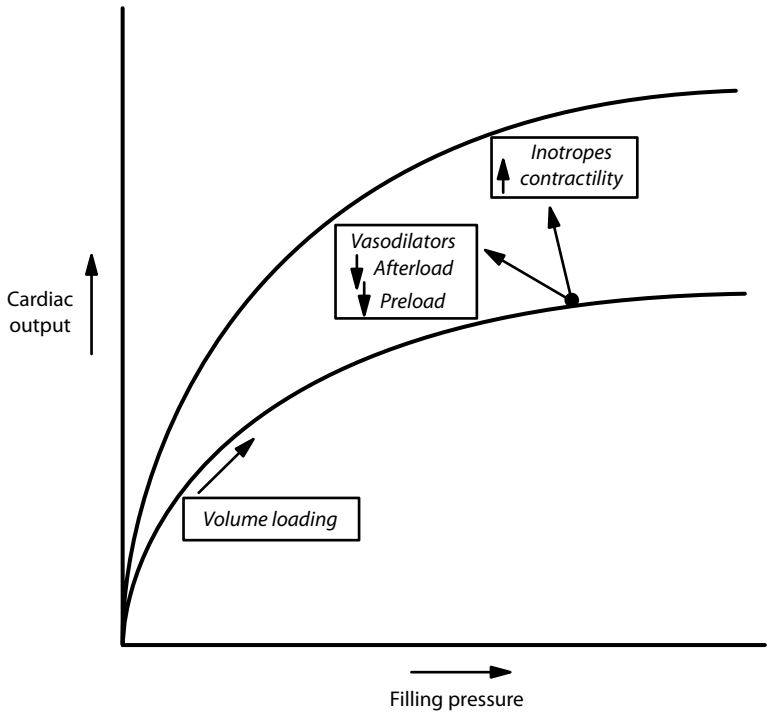

Figure 12.1 Effect of increasing right atrial filling pressures, vasodilator drugs, and inotropes on cardiac output (Frank–Starling curve).

Table 12.5 Vasoactive drugs used for hemodynamic support

Effect of vasoactive drugs			
Drug	**Site of action**	**Dose**	
Dopamine	β1 effects on myocardium; peripheral α effects at high doses; indirect release of noradrenaline; renal vasodilation through dopaminergic receptors in kidney	1–10 μg kg^{-1} min^{-1} β effects 10–20 μg kg^{-1} min^{-1} α and β effects >20 μg kg^{-1} min^{-1} α effects	
Dobutamine	β1 effects on myocardium; weak α and β2 effects at periphery	5–15 μg kg^{-1} min^{-1}	
Epinephrine	β1 effects on myocardium; β2 effects at periphery; peripheral α effects	0.01–0.1 μg kg^{-1} min^{-1}	
Norepinephrine	Predominantly α effects; potent vasoconstrictor; pressor with only minimal inotropic properties	0.01–0.1 μg kg^{-1} min^{-1}	
Milrinone	Phosphodiesterase inhibitor; acts by increasing cGMP; vasodilator and inotropic effects	0.33–1 μg kg^{-1} min^{-1}	
Vasopressin	Acts on V1 receptors in the vascular	0.002–0.0004 μg kg^{-1} min^{-1}	Bed via cAMP; no effect on heart rate

Note: cAMP: cyclic adenosine monophosphate.

which alters the pharmokinetics of medications administered. Fluid balance in the newborn depends on a balance between fluid loss (evaporative, renal, gastrointestinal tract [GIT]) and the intake required for maintaining organ perfusion and growth. Full maintenance fluid requirements for the nonventilated term newborn commence at 60 mL/kg per 24 hours on the first day of life and increase to 100–150 mL/kg per 24 hours by day 7. Fluids are administered as saline 0.9% or 0.45%, with dextrose 5%–10%. Losses from the gastrointestinal (GI) tract due to nasogastric suction, enterocolic fistulas, or high-output stomas can be underestimated and should be measured and replaced.

The hormonal stress response to surgery includes increased release of ADH and cortisol. Anesthetic medications, opiates, and PPV also increase ADH release, causing the infant to retain free water and excrete more concentrated urine. Using hypotonic intravenous solutions as maintenance fluids results in further accumulation of electrolyte free water and can cause hyponatremia.[45,46] All infants on intravenous fluids should have daily assessment of fluid requirements and serum electrolyte levels. When a newborn is on ventilatory support, his/her fluid intake is reduced to 70% of normal requirements as humidification of the ventilator gases reduces insensible fluid loss from the lungs.

A urine output of >1 mL/kg per hour is accepted as adequate and reflects sufficient volume preload and organ perfusion. Short periods of oliguria may follow surgery due to increased ADH levels, but persistent oliguria or anuria needs further management as it may indicate prerenal, postrenal, or intrinsic renal impairment. Prerenal failure is generally due to decreased renal blood flow associated with fluid loss or inadequate fluid resuscitation in a sick infant. A fluid bolus of 20 mL/kg crystalloid or colloid may restore circulating blood volume and renal perfusion. If there is no urine produced following an initial fluid bolus, further fluid administration may be required. Intrinsic renal failure is an infrequent but more serious complication. It is also more difficult to manage. Causes include congenitally abnormal kidneys (cystic or dysplastic), prolonged intraoperative renal ischemia, or vascular abnormalities of the kidney. Drugs such as indomethacin, nonsteroidal anti-inflammatories, and aminoglycosides can cause intrinsic renal damage. If red cells, casts, or protein is found on urinalysis, in association with high urinary sodium losses, it is more likely to be intrinsic renal disease rather than prerenal failure. Management of renal failure focuses on elimination of causes, fluid restriction, and treatment of hyperkalemia. Peritoneal dialysis may be used to support renal recovery.[47] Renal replacement therapy in the form of continuous hemofiltration is not generally performed in newborns, due to availability of suitable equipment and the risks of systemic heparinization.

Temperature regulation and metabolism

Temperature: To maintain a normal body temperature, the neonate has to balance heat loss with heat production. With a large surface area–to–body ratio, the neonate tends to lose heat rapidly by conduction, convection, evaporation, and radiation. The newborn has a limited ability to raise its body temperature through heat production from metabolism of brown fat stores and glucose. This is inability is exaggerated in the premature infant, who is poikilothermic and vulnerable to cold-induced metabolic acidosis, hypoglycemia, increased oxygen consumption, and weight loss. Critically

ill neonates need to be nursed in a warm environment to protect them from the effects of cold stress. If hemodynamically stable, the infant is nursed in an incubator with an internal temperature regulated at 32°C–36°C, which will eliminate conductive and convective heat losses. If the infant needs to be nursed outside the incubator, a radiant warmer bed or platform may be used.

Metabolism—Glucose metabolism is immature in the newborn period, and the sick infant may develop hypoglycemia rapidly. This is as a result of diminished glycogen stores (inadequate hepatic stores in the premature infant or depletion from catecholamine-stimulated breakdown in stress) or due to hyperinsulinism in diabetic mothers. Infants born with intrauterine growth retardation are also vulnerable to development of hypoglycemia due to reduced hepatic gluconeogenesis. Failure to recognize and treat neonatal hypoglycemia results in seizures and cerebral injury. Neonates who are not feeding require maintenance fluid containing dextrose, usually 10%. Blood glucose measurement should be performed regularly as part of normal nursing care. Glucagon and steroid administration is occasionally required to bring the blood sugar level into the normal range (2–6 mmol). Infants receiving intravenous dextrose or total parenteral nutrition may experience rebound hypoglycemia if the infusion is stopped abruptly due to increased blood insulin levels.

Hypocalcemia is common in the newborn period, especially in critically ill newborns, infants of diabetic mothers, and infants who have received large volume blood transfusion. Measurements of total serum calcium do not accurately reflect the level of ionized calcium in the blood. Reduced circulating calcium levels can cause seizures, apnea, and low cardiac output as the neonatal myocardium is very sensitive to changes in calcium serum levels. Replacement using intravenous calcium infusion must be carried out using central venous access as calcium is extremely irritant to small peripheral veins and tissues.

Fluid and electrolyte balance in the newborn

JUDITH MEEHAN, JOSEPH CHUKWU, WINIFRED A. GORMAN, AND ELEANOR J. MOLLOY

INTRODUCTION

Infants are born into a low-humidity, gaseous environment from the liquid intrauterine world. Term and preterm neonates have different fluid requirements and electrolyte changes to older children and adults especially at this time of rapid postnatal transition.

WATER DISTRIBUTION IN THE FETUS AND THE NEWBORN INFANT

Fetal body composition alters progressively throughout pregnancy. Throughout pregnancy, the amount of protein and fat in the fetus increases. Preterm neonates have more water, and they may lose 10%–15% of their weight in the first week of life. At 1 kg birth weight (approximately 28 weeks gestation), the fetus comprises about 80% of its weight as water; by full term, water content is 75% and by 3 months of age (~5 kg) 60%.[1–3] Small for gestational age (SGA) preterm infants may have a higher proportional body water content: 90% for SGA infants versus 84% for appropriate for gestational age (AGA) infants at 25–30 weeks gestation.[4] At 23 weeks gestation, infants are composed of 90% water comprising 60% extracellular fluid (ECF) and 30% intracellular fluid (ICF; Figure 13.1).

The total intracellular water content of the fetus and the newborn infant's body increases directly in proportion to cell mass. Twenty-five percent of the weight of the very immature fetus early in pregnancy is intracellular water, and this increases to 35% at birth and 40% by 3 months of age. Body fat content increases from about 1% in the very early fetus to 15% at birth and 30% at 3 months of age.[1] Fat has a low water content.[1] The SGA infant with a low body fat content has a greater proportion of body weight as water than the AGA infant.

FUNCTIONAL ADJUSTMENTS TO POSTNATAL LIFE

Renal blood flow

Functional nephrons are first present in the fetus at approximately 8 weeks gestation. Nephrons develop in a centrifugal pattern with juxtamedullary nephrons developing first. The full complement of glomeruli is present by 34 weeks gestation. Renal blood supply arises from the aorta between T12 and L2, a relationship that remains constant between 24 and 44 weeks gestation. As the renal arteries divide into segmental end arteries, the renal tissue in their area of distribution is very vulnerable to ischemia, thus follows the recommendation that umbilical artery catheters should not be positioned between T12 and L3.[5,6]

Renal blood flow and glomerular filtration rate (GFR) *in utero* increase gradually with gestational age. Growth of nephrons accounts for the increases in GFR in the fetus. Vascular resistance is high in the fetal kidney and restricts renal blood flow and glomerular filtration *in utero*. The proportion of cardiac output that is distributed to the kidneys during fetal life is about 2%–3%.[5–7] It increases to about 6% during the first week of life and approximates 15%–18% during the first month of life. In adults, the kidneys receive 20%–25% of the cardiac output. The low renal blood flow during fetal life results from a high renal vascular resistance. Factors that may contribute to renal dysfunction in neonates include prematurity, medication (gentamicin, cephalosporin, NSAIDs, Frusemide), hypoxia, congenital renal tract anomalies, and excessive fluid loss.

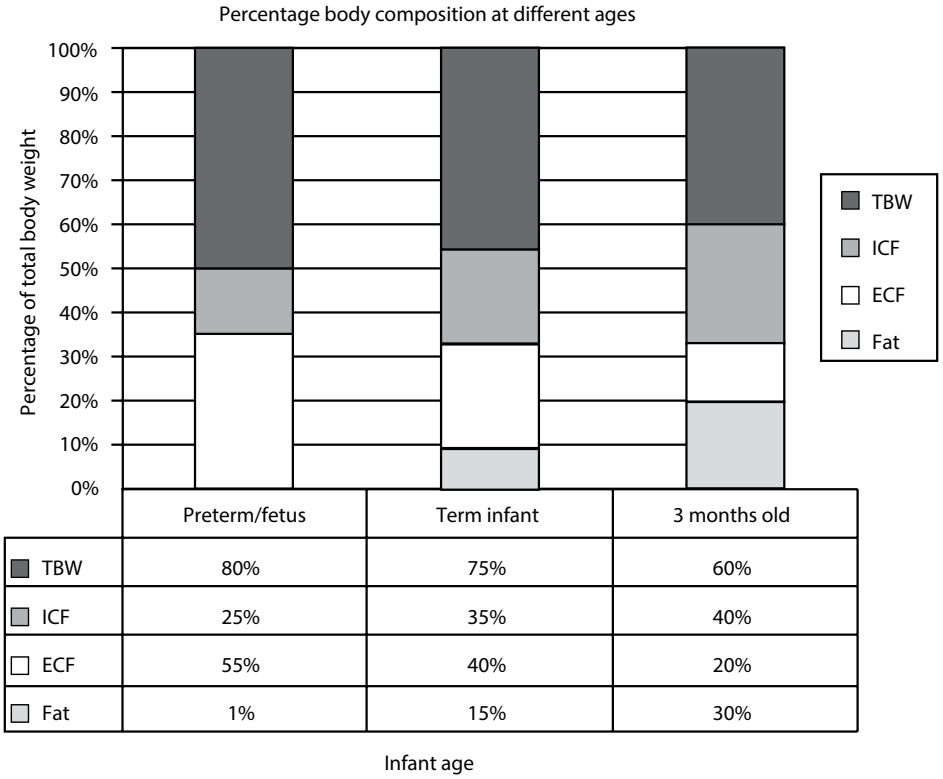

Figure 13.1 Body fluid/fat composition at different ages. TBW: total body water; ICF: intracellular fluid; ECF: extracellular fluid.

Glomerular filtration rate

Glomerular filtration begins between 9 and 12 weeks gestation in the human fetus and contributes to amniotic fluid. In fetal sheep, GFR increases by 2.5 times during the last trimester and parallels the rise in fetal body weight and kidney weight.[8–10] At delivery, there is a positive correlation between GFR and gestational age in newborn infants delivered between 27 and 43 weeks gestation.[11]

In the first 24 hours after delivery, there is a threefold increase in GFR in the term but not preterm infant, although there is no increase in total renal blood flow or in systemic blood pressure. Changes in GFR at birth may be influenced by plasma adrenaline and noradrenaline,[12,13] renin–angiotensin, prostaglandin, arginine vasopressin,[14–16] and plasma cortisol.[17] Indomethacin use in the preterm neonates has been shown to increase the resistance of the renal vascular bed thereby decreasing renal perfusion.[18] Each of these or a combination of these hormones may influence glomerular filtration by decreasing glomerular vascular resistance and recruiting superficial cortical nephrons.

WATER HOMEOSTASIS

The diluting segment of the distal tubule and ascending limb of the loop of Henle develops relatively early in nephrogenesis. When challenged with a water load, both the term and the preterm infants can dilute their urine to osmolalities to 50 and 70 mOsm/kg water, respectively. Glomerular filtration, however, is low, and this limits the quantity of urine that can be excreted even in the presence of a potent dilutional capacity. The newborn kidney of both the term and preterm infants has relatively low osmolality in the renal medulla, and this limits the effectiveness of the countercurrent concentrating mechanism in the loop of Henle.[19,20] In the term infant, urine can be concentrated to a maximum of 600–700 mOsm/L, considerably less than that of 1200 mOsm/L in the older child or adult. Thus, both the preterm and full-term neonates are unable to handle either fluid deprivation or overload, underlining the need for accurate assessment of fluid requirements.[21]

Immediately after birth, a physiological acute isotonic volume contraction occurs predominantly in the extracellular water with the corresponding postnatal weight loss. Weight loss is greater and lasts longer in infants with less advanced gestational age.

Insensible water loss

Insensible water loss is the continuous invisible loss of water by evaporation that occurs from the skin and lung surface. Insensible water loss needs inclusion in the estimation of total fluid requirements.[22] Transepidermal water loss (TEWL) accounts for about two thirds of insensible water loss, while respiratory water loss accounts for one third. Insensible water loss is greater in less mature infants.[23]

Sweating

Sweating occurs to only a very limited extent in response to a thermal stimulus in the term infant, despite the fact that the full complement of sweat glands is present at birth. Although even the most immature infant soon develops the ability to sweat in response to heat stress, the efficiency of sweating as a thermoregulatory process is poor.[24]

Transepidermal water loss

Evaporation of water from the skin surface occurs continuously by diffusion.[25,26] The quantity of water lost is determined by the relative humidity of the infant's surrounding atmosphere particularly in the preterm infant: skin maturation - immature skin keratinization.

TEWL is closely related to thermal balance—there is heat loss whenever water evaporates from a surface (1 g water = 0.58 kcal of heat loss). In a term baby under stable environmental conditions, TEWL can be elevated, accounting for as much as 70 cal/kg/day heat loss (more than half of the caloric intake of the preterm infant). Preterm infant TEWL is greatly increased as gestational age decreases due to the large ratio of surface area to weight and the immature epidermal barrier to water. TEWL from the skin is exaggerated by postnatal trauma to the skin, for example, from adhesive tape applied to the skin for attachment of monitors. Incidentally, neonatal skin barrier dysfunction using TEWL predicts food allergy at 2 years of age, supporting the concept of transcutaneous allergen sensitization.[27]

In addition, placing impermeable plastic sheets over and under the baby or the use of plastic bags can significantly reduce TEWL of the infant surgical patient.[28] After birth regardless of gestation, the skin matures and skin permeability to water falls. However, in the extremely preterm infant, this maturation may be extremely slow and extracellular water loss has been shown to be higher than normal at 28 days postnatal age.[29,30] TEWL gradually decreases over the first 7 days of life and is significantly lower in infants whose mothers had received prenatal steroids. However, Jain et al. failed to demonstrate any maturational effect of antenatal steroids on transepidermal loss in preterm infants.[31–33] Maximizing incubator humidity can reduce TEWL.[34] Insensible water loss in infants weighing <1 kg is reduced to <40 mL/kg/day if ambient humidity is above 90%.[35]

Respiratory water loss

Respiratory loss represents 39% of insensible water loss in term infants. Inspired air becomes fully saturated with water in the upper respiratory tract, and some water is lost as this air is expired. Similarly, tachypnea increases water loss. The relative humidity of the air before inspiration also has an influence; the higher the humidity, the less water needs to be added and the less lost. Ventilated infants inspire humidified air delivered, reducing respiratory water loss by a third.[36]

FLUID AND ELECTROLYTE MANAGEMENT

Infants admitted to a neonatal intensive care unit who are unable to exclusively feed orally require careful management of fluid and electrolyte balance. Additional difficulties may occur if the infant is preterm and if, as frequently happens in babies requiring surgery, there are additional losses from the intestine or the kidneys as a result of a complex surgical problem. When planning maintenance fluid therapy for an infant, all the variables that have already been discussed that may influence fluid requirements must be taken into account. Any guidelines for fluid and electrolyte therapy must be modified to suit an individual infant's requirements. Tables 13.1 and 13.2 give some guidelines that may be used and modified appropriately.[37] Preterm infants

Table 13.1 Fluid requirement in the newborn

	Fluid volume (mL/kg)	Fluid type
Baby Nursed in Incubator		
Day 1	60	10% dextrose/TPN
Day 2	80	Plasmalyte in 10% dextrose/TPN
Day 3	100	Plasmalyte/10% dextrose/TPN
Day 4	120	Plasmalyte/10% dextrose/TPN
Day 5	150	Plasmalyte/10% dextrose/TPN
Baby Nursed under Radiant Warmer		
Day 1	80	10% dextrose/TPN (5% dextrose if Bwt < 1500 g)
Day 2	100	Plasmalyte in 10% dextrose/TPN
Day 3	120	Plasmalyte/10% dextrose/TPN
Day 4	140	Plasmalyte/10% dextrose/TPN
Day 5	150	Plasmalyte/10% dextrose/TPN

Note: Restricted fluids—two thirds of normal maintenance fluids. Very low birth weight infants frequently require even higher initial rates of fluid administration and frequent reassessment of serum electrolytes, urine output, and body weight.

Table 13.2 Maintenance electrolyte therapy

	Per kg/day
Sodium	2–4 mmol
Potassium	1–3 mmol
Calcium	5–10 mL of 10% calcium gluconate (1.125–2.25 mmol calcium)

<1.5 kg should be commenced on total parenteral nutrition in the first few hours of life to optimize their nutrition and then, expressed breast milk once available. Further discussion of neonatal enteral and parenteral nutrition is beyond the scope of this chapter.

Increased fluid requirements may occur in the following circumstances:

- *Low birth weight infants* <1.5 kg. The very low birth weight infant has a very high insensible loss of fluid and thus increased requirements for free water.
- *Phototherapy.* Phototherapy increases insensible water loss by evaporation; thus, fluid intake should be increased by 10 mL/kg/day per number of phototherapy unit light used in the infant >1.5 kg and 20 mL/kg/day per number of lights used with birth weights <1.5 kg.[38,39]
- *Radiant warmer.* Nursing on a radiant warmer increases insensible fluid loss by a mean of 0.94 mL/kg/h[40] when compared with incubators. This increased water loss is not prevented by using a heat shield but may be prevented by using a plastic blanket.[40–42] Use of a humidified incubator is preferable especially in preterm babies.
- *Polyuric renal failure (especially in infants <26 weeks gestation).* Maintenance fluids will require very frequent readjustment guided by regular monitoring of the weight and the serum electrolytes.

Maintenance fluid therapy may need to be decreased in the following circumstances:

- Inappropriate ADH secretion
- Congestive heart failure
- Oliguric renal failure
- Patent ductus arteriosus

Conservative patent ductus arteriosus (PDA) management involves fluid restriction to a total fluid intake of 120 mL/kg/day.[43] A high PDA closure rate (up to 100%) in preterm infants with PDA managed conservatively with fluid restriction (130 m/kg/day) and adjustment of ventilation (reducing inspiration time and increasing the peak end expiratory pressure) may be achieved.[44] The detailed management of PDA with pharmacotherapy and surgery is beyond the scope of this chapter.

In assessing the infant's water requirements, one needs to evaluate weight change, urine output, specific gravity and osmolality, serum sodium and creatinine, and blood urea and osmolality. Normal urine output is 2–4 mL/kg/h. In the first 24 hours of life, urinary output may be very low or even absent. During recovery from a severe illness associated with fluid retention or edema, polyuria may occur. A physiological diuresis (water loss) of up to 10% of body weight occurs over the first 4–5 days of life. This diuresis has the effect of decreasing total body water content by contracting the ECF volume. It is greater in the preterm infant whose total body water content is higher than that of the term infant. This water loss occurs despite usual fluid intakes and is typically accompanied by a negative sodium balance even when sodium is provided.

High fluid intake (>170 mL/kg/day) increases the likelihood of symptomatic patent ductus arteriosus.[45] High fluid intake and or high sodium intake may also increase the likelihood of respiratory complications both in the short term and in the longer term by increasing the frequency of chronic lung disease (CLD).[46,47]

Sodium regulation

Maintenance of normal serum sodium (135–140 mmol/L) is principally controlled by the kidneys. The amount of sodium that can be excreted is limited by the GFR, and the ability of the kidney to excrete a sodium load is diminished as compared with adults and falls progressively with decreasing gestational age.[48–50] Preterm infants have a higher fractional sodium excretion than full-term infants.[48] Extrauterine existence accelerates tubular sodium reabsorption but not GFR, whose maturation is related to postconceptual age. Al-Danhan et al.[48,49] demonstrated that preterm infants of <30 weeks gestation require a minimum of 5 mmol/kg/day of sodium and those of 30–35 weeks gestation require 4 mmol/kg/day to achieve a positive sodium balance and maintain normal serum sodium.

Intestinal absorption of sodium in the very preterm infant is low and improves progressively with increasing gestational age.[49] Neonates undergoing intensive care may gain significant amounts of fluid and sodium from drugs, bronchial lavage, and flushing of catheters, sources that are often overlooked. Hypernatremia may occur, especially in the very low birth weight infant, and may have adverse effects.[51]

Antenatal steroids induce maturation of renal tubular function. Infants who have been exposed to prenatal steroids have an earlier diuresis and natriuresis.[31] Randomized controlled trials have shown that early sodium administration increases the risks of hypernatremia, particularly if TEWL is high and water intake is limited, and increases the risks of respiratory morbidity by impeding the normal, physiological loss of ECF. Subsequently, once nutritional intake is sufficient to support growth, the extremely preterm infant is at risk of chronic sodium depletion. At this stage, an intake of at least 4 mmol/kg/day is required, or more particularly in the absence of antenatal steroid exposure.[52–56]

Renal response to antidiuretic hormone

The human fetal pituitary secretes antidiuretic hormone (ADH) from 12 weeks gestation onward. Labor and delivery are associated with a surge in ADH secretion in cord blood. Both term and preterm infants are capable of an appropriate ADH response to stimuli. Although ADH levels in newborn infants are similar to adults, the antidiuretic response to ADH is blunted because a lower concentration gradient in the renal medulla lessens its effectiveness and low numbers of ADH receptors. Excess ADH can cause a drop in urine output and hyponatremia.[14,57]

Factors that result in excess or inappropriate secretion of ADH (SIADH) in the newborn include birth asphyxia, surgery, hypoxia, severe lung disease, positive pressure ventilation, intracranial hemorrhage, and pneumothorax. SIADH results in weight gain, hyponatremia, and oliguria. SIADH is diagnosed by documenting hyponatremia in association with low serum osmolality and high or normal urine osmolality and high urinary sodium due to continued excretion of sodium in urine despite low serum sodium. There is usually no evidence of fluid depletion. It is also important to note that the renal, adrenal, and thyroid functions are usually normal in SIADH. Management is by fluid restriction in addition to alleviating the primary cause.[58]

Sodium balance

Sodium is not required during the first 24 hours of life, during which time urine and sodium output are low. Sodium supplementation of 2–4 mmol/kg/day should be given when weight loss of approximately 5%–10% of birth weight and postnatal diuresis have occurred.

Hyponatremia, defined as Na+ <130 mmol/L, may occur in the following circumstances:

- Laboratory error.
- Excess antidiuretic hormone secretion, where low urinary loss of water results in dilutional hyponatremia.
- Large renal tubular losses of sodium as occurs in extreme prematurity or polyuric renal failure.
- Congestive heart failure with dilutional hyponatremia.
- Diuretic therapy with loss of sodium via the renal tubules.
- Hypoadrenalism: congenital Addison's disease, septic shock with adrenal failure, salt-wasting adrenogenital syndrome.
- Maternal hyponatremia.[59]
- Factitious hyponatremia as a result of hyperglycemia or hyperlipidemia.
- Inadequate sodium intake in preterm infants with excessive renal sodium loses.
- Excessive large intakes of free water or electrolyte-free solutions like dextrose water.
- Congenital syndromes such as Bartter syndrome, which is a genetic defect caused by a defect in the kidneys' ability to reabsorb sodium. This results in a rise in rennin and aldosterone, and potassium wasting in addition to excess sodium loss through the urine.

Hypernatremia, serum sodium >145 mmol/L, may occur in the following circumstances:

- Laboratory error
- High insensible water loss, which is incompletely replaced
- High urinary water losses, which are not replaced
- Maternal hypernatremia
- Deficiency of antidiuretic hormone
- Rarely, excessive administration of Na+ in intravenous fluid flushes
- Excessive sodium bicarbonate administration in infants with metabolic acidosis

Hypernatremia and fluctuations of sodium seem to be related to early severe intraventricular hemorrhage (IVH) among preterm infants,[60,61] and increasing intake of sodium appears to be a modifiable risk factor for IVH in very low birth weight infants. The association of high sodium intake with IVH was of similar magnitude to traditionally recognized risk factors such as pneumothorax.

Potassium balance

Potassium is predominantly an intracellular ion. No potassium is required on the first day of life. After this, intakes of 1–3 mmol/kg/day should replace losses and maintain a normal serum potassium of 3.5–5.8 mmol/L (Table 13.2). Potassium should be cautiously administered in infants with renal dysfunction and the very low birth weight infant whose ability to excrete potassium may be limited. Early non oliguric hyperkalemia may occur in 30%–50% of infants with birth weight <1 kg as a result of a potassium shift from intracellular to extracellular space. Hyperkalemia will be exaggerated by hypoxia, metabolic acidosis, catabolic stress, and oliguria. The hyperkalemia may be severe enough to cause life-threatening arrhythmias.[8,62–65]

Hyperkalemia, serum K+ >6 mmol/L in a sample that is not hemolyzed, becomes concerning when >6.5 mmol/L or if ECG changes occur. ECG changes in hyperkalemia vary from peaked T waves, as the earliest sign, to a widened QRS complex, bradycardia, tachycardia, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation

Hyperkalemia may occur in the following circumstances:

- Laboratory error or hemolysis of blood sample
- Severe metabolic acidosis: with each 0.1 pH drop, serum potassium increases by 0.6 mmol/L
- Tissue cell death with release of intracellular potassium, e.g., release of K+ from neuronal cells and RBCs post IVH, trauma, or surgery
- Acute renal failure
- Very low birth weight in the absence of renal failure

- Very low birth weight in the absence of antenatal steroids
- Adrenal insufficiency secondary to acute adrenal failure as in sepsis/shock or congenital adrenal hyperplasia
- Severe hemolytic anemia

Management of Hyperkalemia (Figure 13.2)

- Avoid potassium in all infusions in the first day of life.
- Infants born <28 weeks gestation should have serum potassium levels recorded from 12–48 hours of age. Blood gas analysis will identify the neonate with rising potassium levels. Laboratory measurement of serum potassium should be performed 12 hourly for the first 48–72 hours of life.
- Only blood from umbilical arterial line, peripheral arterial line, arterial stab, or free-flowing venous sample should be used.
- Treatment of hyperkalemia should commence if serum K+ ≥7 mmol/L confirmed on a nonhemolyzed arterial/venous sample and/or ECG changes are present and serum K+ ≤7 mmol/L.
- ECG changes include tall peaked T waves, prolonged PR interval, small/absent P waves, widening of the QRS complex, and asystole.

Treatments used in premature infants with non-oliguric hyperkalemia aim to decrease the arrhythmogenicity of hyperkalemia, redistribute potassium into the intracellular space, or remove potassium from the body.[66]

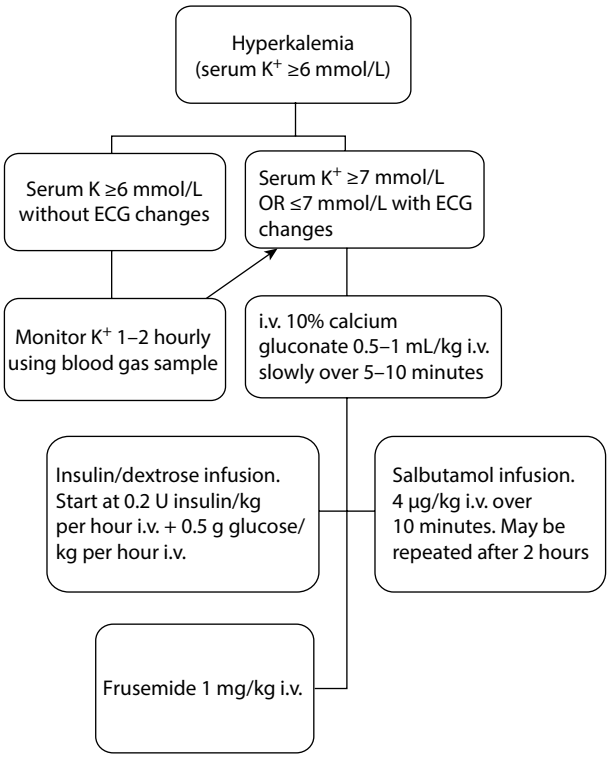

Figure 13.2 Management of hyperkalemia.

Sodium bicarbonate is not recommended. If acidosis is present, the underlying cause should be treated. Ion exchange resins are also not recommended. They have been shown to cause intestinal obstruction and perforation. Also gastric masses found at autopsy were devoid of potassium, indicating that no exchange had occurred. A recent Cochrane study of interventions for neonatal non-oliguric hyperkalemia found limited information from small studies of uncertain quality and made no firm recommendations for clinical practice. The combination of insulin and glucose is preferred over treatment with rectal cation–resin for hyperkalemia in preterm infants. Both the combination of insulin and glucose and salbutamol (albuterol) inhalation deserve further study. Other potentially effective interventions for non-oliguric hyperkalemia (diuretics, exchange transfusion, peritoneal dialysis, and calcium) have not been tested in randomized controlled trials.[67]

CAUSES OF HYPOKALEMIA

Hypokalemia, serum potassium <3.5 mmol/L, may occur in the following circumstances:

- Laboratory error.
- Alkalosis lowers serum potassium by shifting the potassium load intracellularly, but does not lower total body potassium.
- Polyuric renal failure.
- Gastrointestinal losses through vomiting or diarrhea or pooling of fluid in a "third space," such as dilated loops with intestinal obstruction.
- Diuretic therapy.
- Inadequate intake.
- NG aspirate losses not replaced with appropriate fluids.
- Bartter syndrome as mentioned previously, which results in potassium wasting.

Hypokalemia predisposes to cardiac arrhythmias, paralytic ileus, urinary retention and respiratory muscle paralysis. Thus potassium balance must be carefully monitored, taking into account the influence that pH may have on the serum potassium, in that alkalosis shifts potassium which is predominantly an intracellular ion into the cells and acidosis has the reverse effect and that both hyper- and hypokalemia will have adverse effects.

Acid–base balance

Normal values for pH are similar to those in the adult; however, pCO_2 and serum bicarbonate are both slightly lower in the newborn infant than in the adult.[58,59] The lungs and the kidney both have important roles in the maintenance of acid–base balance. The lung excretes volatile acid formed during metabolism as CO_2. Respiratory failure will cause accumulation of CO_2 and respiratory acidosis.

METABOLIC ACIDOSIS

The normal kidney has a vital role in regulation of serum bicarbonate. In mature subjects, serum bicarbonate is maintained at approximately 25 mmol/L, but preterm infants have a lower threshold.[68] The kidney also has an important role in the excretion of nonvolatile acid (mainly sulfur-containing amino acids) produced by metabolism.

Causes of metabolic acidosis

1. Perinatal asphyxia
2. Severe hypotension with impaired tissue perfusion
3. Acute renal failure
4. Acute diarrhea and dehydration
5. Excess ileal loss
6. Excess protein administration, e.g., excess amino acid in parenteral nutrition
7. Inborn errors of metabolism (e.g., organic acidemia)
8. Sepsis

Acute metabolic acidosis is common in the critically ill newborn. Treatment requires management of the underlying cause. Sodium bicarbonate may be used for severe acidosis by giving a dose of 1–2 mmol/kg of 4.2% sodium bicarbonate diluted in equal volume of water. There is currently no evidence from randomized controlled trials to support its routine use in neonatal resuscitation.[69] Its effect on morbidity and mortality has not been well demonstrated. There is controversy about the value of intravenous sodium bicarbonate for correction of metabolic acidosis.[70] It is no longer recommended for resuscitation in newborn infants, and although it may correct acidosis in hypotensive shocked infants, this has not been shown to result in improvement in blood pressure or perfusion.[71] Sodium bicarbonate infusion has potential side effects. Myocardial function may be depressed from the osmolar load with severe acidosis. Paradoxical intracellular acidosis may occur as well as a reduction in cerebral blood flow and increased risk of IVH. Use of sodium bicarbonate is therefore discouraged unless the infant has prolonged acidosis not responsive to other therapies including adequate ventilation.

Causes of metabolic alkalosis

Persistent vomiting causes hypochloremic alkalosis and body potassium depletion. This may occur with untreated pyloric stenosis or upper intestinal obstruction. Correction is by replacement of fluid, sodium chloride, and potassium. Rehydration and correction of depleted electrolytes will be followed by correction of the metabolic alkalosis. Chronic respiratory acidosis as in CLD may cause renal re-regulation of the sodium bicarbonate level at a higher threshold until pH is normal. Infants with chronic hypercapnia regularly have a serum bicarbonate of greater than 30 mmol/L. Permissive hypercapnia or controlled ventilation is a strategy adopted to limit the damage done by excessive mechanical ventilation pressures or volumes to the lungs in order to decrease the incidence of CLD.[72]

Glucose homeostasis

Glucose is the most important substrate for brain metabolism and whereas ketones, glycerol and lactate can be used, a continuous supply of glucose is essential for normal neurological function.[73,74] Fetal blood glucose is identical to that of maternal blood glucose since passive transfer of glucose occurs across the placenta.

HYPOGLYCEMIA

Immediately after delivery, blood glucose falls to ~2.5 mmol/L (45 mg/dL) in the term infant. Following delivery a combination of hormonal responses (glucagon, growth hormone, thyroxine) and oral feeds or in their absence intravenous fluids, serve to maintain blood glucose within a normal range. There is no consensus regarding the definition of hypoglycemia in the neonate.[73,74] Blood glucose levels between 2.5 mmol/L (45 mg/dL) and 7.2 mmol/L (130 mg/dL) are accepted as being safe. Symptomatic hypoglycemia results in cyanosis, apnea, lethargy, seizures, or coma. Blood sugar values represent a continuum, and there is no specific value at which brain-damaging hypoglycemia will always occur.[71,75] However, brain MRI scans after symptomatic neonatal hypoglycemia (median glucose level 1 mmol/L) without evidence of hypoxic–ischemic encephalopathy reveal white matter injury in 94% and neurodevelopmental impairment in 64% at 18 months.[76]

In the newborn infant requiring surgery, hypoglycemia is most commonly caused by vomiting or inadequate intake of fluids. Other contributing factors may include prematurity, septicemia, hypothermia, or hyperinsulinism as may occur in an infant of a diabetic mother. Infants with Beckwith–Wiedemann syndrome, who frequently may have omphalocele, commonly have elevated blood insulin levels and severe hypoglycemia.

Blood sugar in the infant at risk should be monitored at the bedside using a bedside screening glucose analyzer. Blood sugars below 2–2.5 mmol/L should be acted upon by giving a feed or a bolus of intravenous 10% dextrose as appropriate for the individual infant. Significant hypoglycemia should be confirmed by laboratory blood sugar before definitive action, such as intravenous glucose being given. This is because all screening methods are not completely accurate at low blood sugar levels.

HYPERGLYCEMIA

A blood glucose >14 mmol/L (250 mg/dL) may cause a hyperosmolar state with glucosuria, osmotic diuresis, and dehydration. This elevated plasma osmolality increases the risk of intracranial hemorrhage at least in the infant of less than 32 weeks gestation. Hyperglycemia most commonly occurs in the very low birth weight infant who is receiving

large amounts of fluids to counteract insensible loss and whose ability to metabolize dextrose or glucose is limited. Hyperglycemia may also be due to defective islet cell processing of proinsulin, insulin resistance nonsuppression of endogenous glucose production during continuous exogenous glucose infusion.[77,78] Infusion of small doses of insulin may be required to counteract intractable hyperglycemia.[77] Extremely low birth weight babies require a higher total dose of insulin for longer periods than low birth weight preterms. Hyperglycemia is related to defective islet beta-cell processing of proinsulin, partial insulin resistance, and failure to suppress hepatic glucose production during parenteral glucose infusion. Exogenous insulin infusion partially reduces endogenous glucose production in preterm newborn infants. This treatment is efficient and safe when used with caution.[77]

After initial hypoglycemia, due to limited glycogen and fat stores, preterm babies often become hyperglycemic because of a combination of insulin resistance and relative insulin deficiency. Hyperglycemia is associated with increased morbidity and mortality in preterm infants, but what should be considered optimal glucose control, and how best to achieve it, has yet to be defined in these infants. In the first week of life, 80% of infants have glucose levels >8 mmol/L, and 32% have glucose levels >10 mmol/L >10% of the time. Independent risk factors for hyperglycemia include increasing prematurity, small size at birth, use of inotropes, lipid infusions, and sepsis. There was a lack of association between the rate of dextrose infused and risk of hyperglycemia in the Neonatal Insulin Therapy in Europe (NIRTURE) Trial.[79] This study included 195 very low birthweight (VLBW) infants randomized in a multicenter study to continuous infusion of insulin at a dose of 0.05 U per kilogram of body weight per hour with 20% dextrose support and 194 to standard neonatal care on days 1 to 7. Early insulin therapy offered little clinical benefit in very low birth weight infants and reduced hyperglycemia but increased hypoglycemia.[80] The use of insulin in preterm infants and prevention of hyperglycemia could also affect immune function, lipid metabolism, growth, and IGF-I generation leading to improved short-term clinical outcomes such as retinopathy of prematurity.[78]

Calcium homeostasis

Calcium has a key role in many physiological processes, including activation and inhibition of enzymes, intracellular regulation of metabolic sequences, secretion and action of hormones, blood coagulation, muscle contraction, and nerve transmission. Ninety-nine percent of total body calcium is in the bones, to which it gives structural support. Only about 1% is in the ECF and soft tissues.[81] Calcium is present in the ECF in three fractions: 30%–50% is bound to protein, principally albumin; 5%–15% is complexed with citrate, lactate, bicarbonate, and inorganic ions; and 5%–15% is ionized—this is the metabolically active fraction of calcium. Calcium concentration reported as mg/dL can be converted to molar units by dividing by 4 (e.g., 10 mg/dL converts to 2.5 mmol/L).[37,82–84] If serum albumin is low, total serum calcium falls, but the serum level of ionized calcium is unchanged. Serum calcium could be corrected for the level of serum albumin using the formula

$$\text{corrected calcium} = (0.8 \times [\text{normal albumin} - \text{neonatal albumin}]) + \text{serum Ca}$$

Hydrogen ions compete with calcium for albumin binding sites. Thus, acidosis increases serum ionized calcium levels without influencing total serum calcium levels. Prenatally, calcium is actively transported across the placenta from mother to fetus against a concentration gradient, which results in fetal hypercalcemia at the end of the last trimester and immediately after birth. Cord serum calcium in the full-term infant is approximately 2.75 mmol/L.[83] In healthy full-term infants, calcium concentrations decrease for the first 24–48 hours and reach a nadir of 1.8–2.1 mmol/L. Thereafter, calcium concentrations progressively rise to the mean values observed in older children. This transient drop in serum calcium is exaggerated in the preterm infant. Metabolic bone disease is a common feature especially in extreme preterm infants less than 28 weeks gestation and results from inadequate supply of nutrients (vitamin D, calcium, and phosphate), prolonged period of total parenteral nutrition, and prolonged period of immobilization. The main features that manifest between the 10th and 16th week of life include decreased bone mineral density, osteopenia with or without other features of rickets.

HYPOCALCEMIA

This is defined as a total serum calcium concentration <2.0 mmol/L in the term infant and <1.7 mmol/L in the preterm infant.[82] Normal serum ionized calcium in the newborn infant is 1–1.5 mmol/L.[83–85]

Causes of hypocalcemia

1. Infants of diabetic mothers
2. Asphyxia
3. Sepsis
4. Di George's syndrome/22q deletion syndrome
5. Diuretics especially frusemide
6. Hypomagnesemia
7. Maternal hyperparathyroidism
8. Prematurity
9. Vitamin D deficiency

Clinical manifestations

The majority of hypocalcemia is asymptomatic. The symptoms when they occur include jitteriness and seizures. An electrocardiographic Q–T_c interval longer than 0.4 seconds may occur.

Management

Early asymptomatic mild neonatal hypocalcemia does not require treatment. Infants receiving intravenous fluids should be provided with calcium gluconate as maintenance. Brown et al.[86] have shown that aggressive attempts at normalizing serum calcium in sick preterm infants may be ineffective and even hazardous; thus, at the least, in the first week of life, maintenance of serum calcium at a level of 2.0 mmol/L is adequate.

Symptomatic hypocalcemia should be treated with a slow infusion of intravenous calcium gluconate (5 mL 10% calcium gluconate = 1.1 mmol = 45 mg elemental calcium). Extreme care should always be taken when infusing calcium as extravasation can cause severe burns to the surrounding skin and subcutaneous tissue. Emergency treatment of hypocalcemia is only required if the infant is symptomatic. Symptoms include jitteriness, seizures, lethargy, poor feeding, and vomiting [bolus 1–2 mL 10% calcium gluconate IV (0.45 mmol = 18 mg elemental calcium) IV slowly]. Symptoms are uncommon at serum calcium above 1.8 mmol/L and become common at serum calcium <1.5 mmol/L. Oral calcium supplements in the form of Calcium Sandoz provides 2.7 mmol (110 mg) elemental calcium 2.5 mL (50 mg) per kg per day may be given with feeds if the infant on feeds has asymptomatic hypocalcemia, requiring treatment. Symptomatic hypocalcemia unresponsive to calcium therapy may be due to hypomagnesemia. This can be treated with 50% magnesium sulfate either intravenously or intramuscularly.[87]

PERIOPERATIVE MANAGEMENT

Preoperative fluid and electrolyte problems in the neonate

Heird and Winters[88] have summarized the metabolic responses of the normal neonate in the first weeks of life. Preoperatively, infants with abnormalities requiring surgery, especially those of the gastrointestinal tract, may have a variety of electrolyte abnormalities.[88–90] If there has been a delay in recognition of gastrointestinal obstruction and the infant has been vomiting for a period of time, he or she will be dehydrated (Table 13.3).

Upper intestinal obstruction, for example, pyloric stenosis, results in loss of hydrochloric acid from the stomach, and small amounts of sodium and potassium. The kidney then conserves hydrogen ions at the expense of potassium and sodium. Bicarbonate is excreted by the kidney along with sodium and potassium, and the urine pH is alkaline.

Potassium and sodium depletion occurs. As loss of potassium and sodium progresses, and the body stores are diminished, the kidney ceases to excrete these ions with bicarbonate. Sodium and potassium are now conserved by the kidney, and hydrogen ion is lost instead causing a severe hypochloremic metabolic alkalosis. Correction must be with adequate fluid-containing sodium chloride and potassium chloride, as body stores of all these ions are depleted. Infants with lower intestinal obstruction, such as Hirschsprung's disease or other intestinal obstructive lesions, may pool large amounts of fluid and electrolytes in dilated intestinal loops; this may result in intravascular dehydration with hyponatremia, hypokalemia, and metabolic acidosis.

Neonates with necrotizing enterocolitis, peritonitis, or septic shock may have "third space" loss of fluid into the peritoneum, pleural fluid, or interstitial tissues with resultant hypoproteinemia and marked interstitial edema. Additionally, many of these infants are ventilated, sedated, and paralyzed. Immobility resulting from paralysis will accentuate peripheral pooling of interstitial fluid. Intravascular dehydration and hypoproteinemia and hyponatremia will result.

Preoperatively, the infant's hydration should be assessed on the basis of weight, pulse, blood pressure, capillary filling time, blood urea, electrolytes, urine output, specific gravity, and electrolyte content.

Intraoperative management

Careful attention to fluid and electrolyte balance intraoperatively is essential, including blood pressure, pulse, and temperature. During major procedures, intravascular lines allow blood pressure and central venous pressure

Table 13.3 Electrolyte composition of body fluids

	Electrolytes (mEq/L)				
Body fluid	**Na+**	**K+**	**Cl–**	**HCO_3**	**pH**
Gastric	70	5–15	120	0	1
Pancreas	140	5	50–100	100	9
Bile	130	5	100	40	8
Ileostomy	130	15–20	120	25–30	8
Diarrhea	50	35	40	50	>7

Disorders of calcium and phosphorous metabolism in infants and children 1988:253–271.

monitoring. Urine output should also be measured and oxygenation and ventilation with blood gases and pulse oximetry.

Loss of fluid and heat from exposed peritoneal surfaces should be taken into account and minimized by keeping the operating room sufficiently warm. Acute blood loss should be replaced.[89]

Postoperative management

Patients who have been adequately managed pre- and intraoperatively may be well hydrated, immediately, postoperatively. If the infant had hypotension, transient renal failure with oliguria may occur and may be managed with fluid restriction and correction of electrolyte abnormalities. Inappropriate secretion of antidiuretic hormone is common and results from pain and/or ventilation, resulting in fluid retention and hyponatremia; thus, care must be taken to avoid overhydration, which will encourage both of these. Respiratory acidosis should be corrected by appropriate ventilation. Metabolic acidosis may occur postoperatively in the infant who is persistently hypotensive or hypoxic or who has ongoing tissue necrosis (i.e., severe necrotizing enterocolitis). This must be addressed by correcting the underlying cause of acidosis and by giving sodium bicarbonate. Fluids lost through nasogastric suctioning or drainage must be replaced at regular intervals by normal saline with maintenance potassium added; if losses are from the small intestine, it has been recommended that a small amount of bicarbonate be also added. Where large fluid losses occur from aspiration, calculation of the electrolyte content of these fluids may help plan replacement (Table 13.3).[87,88]

Nitrogen excretion occurs in neonates postoperatively. Thus, early attention must be given to beginning parenteral nutrition in infants in whom early feeding is not foreseen.

FLUID AND ELECTROLYTE BALANCE IN SEPTIC SHOCK

Many surgical conditions predispose to sepsis and shock, including necrotizing enterocolitis, Hirschsprung's disease with enterocolitis, and volvulus. The risk of septicemia with hypotension is even higher if the infant is also preterm. Shock is a stage of acute cardiovascular dysfunction in which the delivery of oxygen and nutrients is insufficient to meet metabolic demands of the tissues. Endotoxin appears to be the common etiological factor in septic shock.[91,92]

Metabolic substrates, i.e., oxygen, glucose, and fatty acid, are available, but their utilization is impaired causing multiple organ failure. Capillary permeability increases, and fluid and protein leak into the interstitial fluid resulting in tissue edema, hypoproteinemia, and a fall in the intravascular fluid volume. Pulmonary hypertension, followed by marked pulmonary edema, occurs with severe respiratory distress. Myocardial depression results in decreased cardiac output.

Clinical manifestations

Neonatal bacterial septicemia may be fulminant and fatal. A high index of suspicion by the nursing and medical staff is essential. Presenting features are subtle and may be recognized only by an experienced nurse or doctor. The infant may merely appear "off color." Early signs of sepsis include lethargy, irritability, apnea and temperature instability, elevated C-reactive protein, and increased immature to total neutrophil ratio.

Management

Shock must be reversed with rapid infusion of fluid and colloid to replete the intravascular space. Normal saline at a volume of 10–20 mL/kg can be infused over 20–60 minutes.[88] Inotropic agents may be needed to increase cardiac output—dopamine improves cardiac contractility (5–20 μg/kg per minute) and in a low dose (<5 μg/kg per minute) also increases blood flow to the kidneys and the intestine; high doses have the opposite effect. Alternative drugs are dobutamine, milrinone, or isoproterenol. Patients with profound hypotension and myocardial depression may respond only to infusion of epinephrine or norepinephrine. Hydrocortisone at stress doses could be used to treat recalcitrant hypotension not responsive to full doses of inotropes and intravascular volume repletion. Administration of corticosteroids leads to rapid resolution of the hypotension without increasing the risk of spontaneous intestinal perforation, grade III–IV IVH, periventricular leukomalacia, and sepsis (bacterial or fungal). Hyperkalemia results from oliguria and tissue catabolism, and hyponatremia results from increased total body water and inappropriate ADH secretion.

In the Fluid Expansion as Supportive Therapy (FEAST) trial, Maitland et al. randomized 3,141 children over 60 days old with severe febrile illness and impaired perfusion to one of three arms: 20 to 40 mL/kg of 5% albumin, 0.9% saline boluses, or no bolus at all, at hospital admission in six sites located in Uganda, Kenya, or Tanzania. All children received maintenance fluids and the standard of care recommended by guidelines. The primary endpoint was 48-h mortality. Forty-eight-hour mortality was 10.6% and 10.5% in the albumin-bolus and saline-bolus groups, respectively, and 7.3% in the control group. Four-week mortality rates were 12.2%, 12.0%, and 8.7%, respectively. Most deaths (87%) occurred before 24 hours. At a scheduled interim data review in January 2011, with data available from 2,995 children, a data and safety monitoring committee recommended stopping enrollment because it was unlikely that the bolus arms would prove to be superior. The authors could not identify any subgroup in which fluid resuscitation was beneficial, which was remarkable given that many of the baseline characteristics of the children in this study are considered to be important criteria for bolus-fluid therapy.[93] These results may not be directly applicable to a

developed world setting but suggests that future therapy should be directed at a more cautious approach to fluid resuscitation.

ACUTE RENAL FAILURE

Acute renal failure is common in the seriously ill neonate requiring surgery. It may be prerenal as a result of severe dehydration, hypotension, abdominal distension, or sepsis. It may result from congenital severe intrinsic renal disease. It may be obstructive and result from severe obstruction in the urinary collecting system, e.g., urethral valves.[92,94]

Prerenal failure is the most common form of acute renal failure in the surgical neonate, and results from a severe decrease in renal perfusion usually as a result of profound hypotension from blood loss, sepsis, severe necrotizing enterocolitis, or intestinal obstruction with loss of fluid into dilated intestinal loops.

Primary fascial closure of omphalocele or gastroschisis carries the risk of placing the abdominal contents under pressure, which may cause a reduction in cardiac output, hypotension, bowel ischemia, venostasis, and postoperative renal failure. Limited data suggest that an intragastric pressure >20 mmHg or an increase in central venous pressure of 4 mmHg or more indicates the need of a staged repair using a pouch.[95] Additionally, newborn infants with abdominal wall defects have significantly increased fluid requirements preoperatively as major insensible water losses occur when eviscerated bowel is exposed to air, and a perioperative third space is frequently associated. These conditions also favor hypovolemia, hypoperfusion of the kidney, and postoperative renal failure.

Renal vein or renal artery thrombosis, if bilateral, may be associated with acute renal failure. Treatment is by early aggressive fluid replacement until blood pressure normalizes, and then by meticulous adjustment of fluid and electrolyte balance until recovery of renal function occurs. Peritoneal dialysis may be required until renal function recovers. Recovery is associated with a polyuric phase, which also requires ongoing care with replacement of large amounts of water, potassium, and sodium via the kidneys.

Renal failure due to obstruction and due to congenital malformations is often associated with severe irreversible renal diseases not compatible with normal extrauterine life. The focus of care must initially be to decide on the appropriateness of active management. Further discussion of renal failure management is outside the scope of this chapter.

CONCLUSION

Major changes in body composition and in fluid and electrolyte balance occur during the transition to extrauterine life. These changes are even more marked in the preterm infant. The newborn infant who has a disorder requiring surgery has additional possible disorders of fluid and electrolyte balance. Future research and audit of fluid management strategies are vital to prevent hypernatremia, hyperglycemia, and hyponatremia, and adverse neurodevelopmental sequelae.

Nutrition

SIMON EATON AND AGOSTINO PIERRO

INTRODUCTION

The newborn infant requires nutrition not only for tissue maintenance and normal metabolism but also for growth—a term newborn grows at a rate of 25–30 g per day over the first 6 months of life, so that weight has doubled by the age of 5 months. The newborn infant is in a "critical epoch" of development not only for the organism as a whole but also for the individual organs and most significantly for the brain, so a significant period of inadequate nutrition may not only affect short-term outcomes but may also be a risk factor for the long-term menace of stunted mental and physical development. As well as providing the components necessary for increase in tissue mass, adequate provision of the nutrients required to mount an appropriate immune response is extremely important, as infection and sepsis may impair growth and neurodevelopmental outcome.[1] Hence, where indicated, early intervention with appropriate artificial nutritional support is of paramount importance.

The optimum nutritional route is oral enteral feeding; however, artificial enteral feeding or parenteral nutrition (PN) may be required if adequate oral feeds cannot be tolerated. The basic principle underlying choice of feeding routes is that the most physiological route safely possible should be used: gastric feeds are preferred over jejunal feeds, enteral feeds are preferred over parenteral feeds, etc. Various investigators have highlighted the importance of introducing enteral nutrition as soon as possible in surgical neonates. The beneficial effects of minimal enteral feeding on the immune system, infection rate, and liver function have been elucidated.

Growth monitoring

Artificial enteral nutrition and PN are both nutritional interventions, and nutritional outcomes should be assessed in order to determine the effectiveness of these interventions. Growth of all pediatric surgical patients, especially those receiving artificial nutritional support, should be monitored longitudinally using appropriate national charts (e.g., those available from the Royal College of Paediatrics and Child Health in the United Kingdom and Centers for Disease Control and Prevention in the United States). In the absence of national charts, those available from the World Health Organization should be used.

BODY COMPOSITION AND ENERGY REQUIREMENTS OF THE NEONATE

Newborn infants grow very rapidly and have higher energy expenditure and lower caloric reserves than adults, and therefore do not tolerate prolonged periods of starvation. The body composition of newborn infants is markedly different from that of adults: total body water varies from 87% of body weight at 24–25 weeks gestation to 71% at term and 50% in adulthood (Figure 14.1).[2] This decline in body water reflects also an increase in energy content of the body. The ratio between resting energy expenditure (REE, in kcal kg^{-1} day^{-1}) to nonprotein energy reserve (in kcal/kg) gives an approximate estimate of the energy reserve of the infants. This is only ~2 days at 24–25 weeks gestation, increases to ~20 days at term as glycogen and fat stores increase (Figure 14.1),[2] and is in excess of 50 days in the adult, hence the urgent need for adequate caloric intake in very-low-birth-weight (VLBW) and/or extremely-low-birth-weight (ELBW) infants after birth. Early PN in VLBW infants has been shown to be beneficial,[3] although there is controversy on how "aggressive" nutritional intervention should be in preterm infants. Full-term neonates have a higher content of endogenous fat (approximately 600 g) and therefore can tolerate a few days of undernutrition. Nevertheless, adequate nutrition in excess of basic requirements, i.e., enough to support growth, should be instituted as soon as practicable. Although adults following surgery or trauma have increased energy requirements, there is no strong evidence that increased energy should be provided to septic or surgical neonates.[4] The total energy requirement for an ELBW (i.e., <1000 g) preterm infant fed enterally is 130–150 kcal kg^{-1} day^{-1},[5] and that of a term infant is 100–120 kcal kg^{-1} day^{-1},

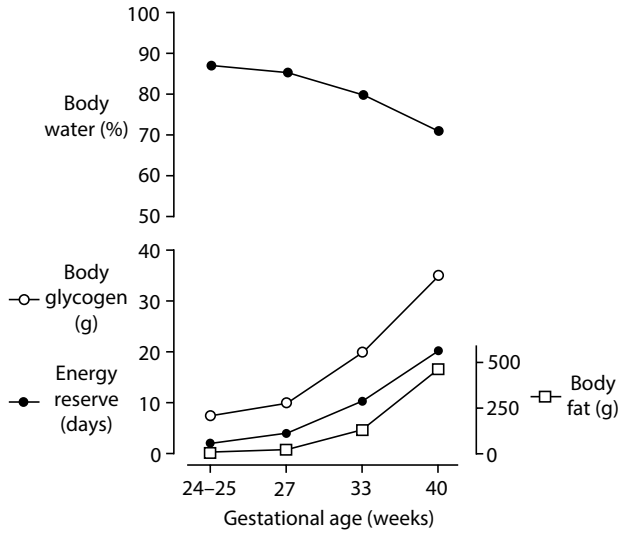

Figure 14.1 Body water and energy stores according to gestational age.

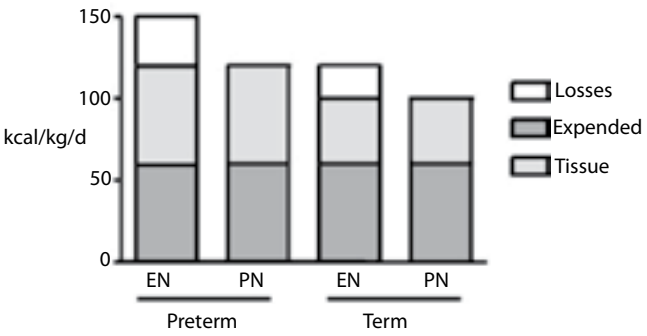

Figure 14.2 Partition of energy metabolism in preterm and term infants receiving nutrition enterally (EN) or parenterally (PN). "Expended" includes basal metabolic rate, activity, the energy expended in laying down new tissue, and thermoregulation. "Tissue" is the amount of energy actually stored in new tissue. "Losses" include losses in stool etc. (Data from Koletzko B et al., Guidelines on Paediatric Parenteral Nutrition of the European Society of Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) and the European Society for Clinical Nutrition and Metabolism (ESPEN), supported by the European Society of Paediatric Research (ESPR), *J Pediatr Gastroenterol Nutr*, 2005, 41 Suppl 2, S1–S87. Tsang RC et al., *Nutrition of the Preterm Infant: Scientific Basis and Practical Guidelines*, 2nd ed., 2005.)

compared to 60–80 kcal kg^{-1} day^{-1} for a 10-year old and 30–40 kcal kg^{-1} day^{-1} for a 20-year old individual.[6] Of the 100–120 kcal kg^{-1} day^{-1} required by the term infant, approximately 40–70 kcal kg^{-1} day^{-1} is needed for maintenance metabolism, 50–70 kcal kg^{-1} day^{-1} for growth (tissue synthesis and energy stored), and up to 20 kcal kg^{-1} day^{-1} to cover energy losses in excreta. Newborn infants receiving total parenteral nutrition (TPN) require fewer calories (110–120 kcal kg^{-1} day^{-1} for a preterm infant and 90–100 kcal kg^{-1} day^{-1} for a term infant),[4] due to the absence of energy losses in excreta and to the fact that energy is not required for thermoregulation when the infant is in an incubator. These data are shown diagrammatically in Figure 14.2, but it should be stressed that energy requirements vary greatly. Several equations have been used to estimate the REE, and therefore the energy requirements, of infants and children. The most frequently used are those of the World Health Organization (WHO),[6] Schofield,[7] and Harris and Benedict.[8] These are based on weight, height, and/or age; are based on measurements of orally fed, healthy individuals; and thus take no account of the abnormal physiology and/or pathology of infants requiring artificial nutritional support. Although adults show large increases in REE following trauma, surgery, or burns or during severe infection, this does not appear to be true for infants, although there are few studies in this area. Critically ill, postsurgical ventilated premature neonates,[9] neonates with necrotizing enterocolitis,[10] and surgical infants (with or without extracorporeal membrane oxygenation [ECMO])[11] were shown to have similar REE values to healthy neonates, whereas others have suggested that REE is increased during neonatal sepsis[12] and that REE correlates with severity of illness during sepsis in neonates.[13] Another study, examining the immediate postoperative response to neonatal surgery, found that there is a peak in REE 4 hours after surgery, which was short-lived, returning to baseline within 12–24 hours after surgery.[14] Thus, there is no clear indication that increased energy should be provided to septic or surgical neonates,[4] although there are scant data on either postsurgical energy metabolism or growth of surgical infants.

REE is directly proportional to growth rate in healthy infants, and growth is retarded during acute metabolic stress. Studies in adult surgical patients have shown that operative stress causes marked changes in protein metabolism characterized by a postoperative increase in protein degradation, negative nitrogen balance, and a decrease in muscle protein synthesis. However, changes in whole-body protein flux, protein synthesis, amino acid oxidation, or protein degradation do not seem to occur in infants and young children undergoing major operations,[15] which led us to speculate that infants and children divert protein and energy from growth to tissue repair, thereby avoiding the overall increase in energy expenditure and catabolism seen in the adult.[10,15]

Nutritional problems in infants and children requiring surgery are not unusual. The real nutritional challenge is not represented by the operation per se but by the clinical condition of the patient. Examples include intrauterine growth retardation in small-for-gestational-age preterm infants, infants who have suffered massive intestinal resection for necrotizing enterocolitis, and infants with motility disorders of the intestine following surgery for atresia, malrotation and midgut volvulus, meconium ileus, or gastroschisis.

Nutritional integrity particularly in the neonatal period should be maintained regardless of the severity of the illness or organ failure due to the limited energy and protein

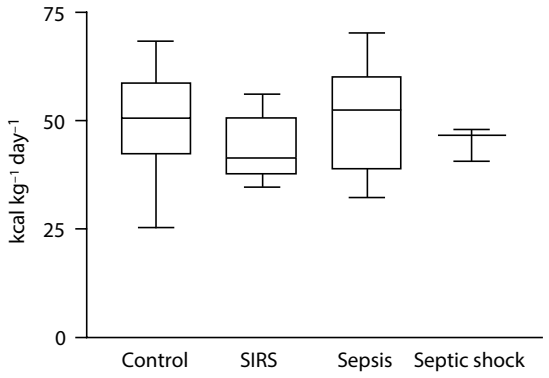

Figure 14.3 Resting energy expenditure in critically ill infants and controls. Indirect calorimetry was performed on infants and children with systemic inflammatory response syndrome (SIRS), sepsis, septic shock, and controls. Results are expressed as median, range, and interquartile range. There were no significant differences between the groups. See Ref. 50.

stores in neonates. Infants and children require nutrition for maintenance of protein status as well as for growth and wound healing. One considerable challenge in pediatrics is represented by nutrition support during critical illness and sepsis. Keshen et al.[16] have shown that parenterally fed neonates on extracorporeal life support are in hypermetabolic and protein catabolic states. These authors recommend the provision of additional protein and nonprotein calories to attenuate the net protein losses.

The existing knowledge on the metabolic response to sepsis in infants is limited. There are conflicting reports on whether critically ill infants are hypermetabolic.[11,17,18] However, most studies suggest that infants with sepsis do not become hypermetabolic[19,20] (Figure 14.3) and that septic neonates with necrotizing enterocolitis do not show any increase in whole-body protein turnover, synthesis, and catabolism.[10] However, the conflicting data may reflect measurements taken at different times in infants with differing degrees of sepsis.[21]

From these studies, it is clear that the metabolic rate and hormonal response to surgery, stress, and sepsis in infants may well be different from that of adults, and therefore, it is not possible to adapt nutritional recommendations made for adults to the neonatal population. It is possible that neonates divert the products of protein synthesis and breakdown from growth into tissue repair. This may explain the lack of growth commonly observed in infants with critical illness or sepsis. Further studies are needed in this field to delineate the metabolic response of neonates and children to trauma and sepsis, explore the relationship between nutrition and immunity, and design the most appropriate diet.

PARENTERAL NUTRITION

Indications

PN should be utilized when enteral feeding is impossible, inadequate, or hazardous, but should be given for the shortest period of time possible and the proportion of nutrition given enterally increased as tolerated. Energy reserves are such that stable term infants can tolerate 3–4 days without enteral feeds before starting PN, if it is anticipated that enteral nutrition may be resumed within this time. Premature neonates have smaller energy reserves, and the time before introducing PN is much shorter.

The most frequent indications in pediatric surgery are intestinal obstruction due to congenital anomalies, although acquired conditions may require PN for variable lengths of time. Although infants with some neonatal surgical conditions, such as gastroschisis, are all likely to receive PN, there are some other congenital anomalies where the use of PN is more controversial, for example, duodenal atresia, in which many surgeons would routinely initiate PN, whereas some surgeons preferentially manage patients without PN by the use of transanastomotic tubes.[22] In addition to congenital bowel obstruction, PN may also be used in cases of postoperative ileus, necrotizing enterocolitis, short-bowel syndrome, gastroenterological indications, and respiratory comorbidity.

Route of administration

As phlebitis may develop with the use of peripheral veins with solutions exceeding 600 mOsm, it is not possible to administer adequate calories peripherally for the growth of ELBW infants, and peripheral veins are only used for short-term, partial, nutritional supplementation. In neonates, the umbilical vessels can be used for provision of PN centrally, although the risk of complications increases if umbilical catheters are used for more than 5 days (arterial) or 14 days (venous).[4] Central venous catheters can either be placed percutaneously directly in a deep vein, with subcutaneous tunneling of the extravascular part of the line, or be a peripherally inserted central catheter (PICC). Although there has been a systematic review comparing outcomes in neonates administered PN through percutaneous central venous catheters versus peripheral cannulae, the authors concluded that there was insufficient evidence to make formal recommendations.[23] For consideration of technical aspects of placement and management, the reader is directed to the European Society for Paediatric Gastroenterology Hepatology and Nutrition (ESPGHAN)/ European Society of Parenteral and Enteral Nutrition (ESPEN) guidelines.[4]

Components of PN

The PN formulation includes carbohydrate, fat, protein, electrolytes, vitamins, trace elements, and water. The caloric needs for TPN are provided by carbohydrate and lipid. Protein is not used as a source of calories, since the catabolism of protein to produce energy is an uneconomic metabolic process compared to the oxidation of carbohydrate and fat, which produces more energy at a lower metabolic cost. The ideal TPN regimen therefore should provide enough amino acids for protein turnover and tissue growth,

and sufficient calories to minimize protein oxidation for energy.

FLUID REQUIREMENTS

As noted previously, the proportion of body weight as water decreases with postnatal age (Figure 14.1). In addition, the proportion of total body water that is extracellular also decreases, from 65% at 26 weeks gestation to 40% at term and 20% in childhood.[24] This contributes to an expected weight loss in the first days of life. Any newborn infant deprived of oral fluids will lose body fluids and electrolytes in urine, stools, sweat, and evaporative losses from the lungs and the skin. The insensible water losses from the skin are particularly high (up to 80–100 mL kg^{-1} day^{-1}) in very-low-birthweight or extremely premature infants.[24] This is due to the very large surface area relative to body weight, to the very thin and permeable epidermis, to reduced subcutaneous fat, and to the large proportion of total body water and extracellular water.[24] The preterm infant requires larger amounts of fluid to replace the high obligatory renal water excretion due to the limited ability to concentrate urine. In surgical newborns, it is not unusual to have significant water losses from gastric drainage and gastrointestinal stoma. Phototherapy may also increase losses. In order to reduce the water losses, it is important to use double-walled incubators, to place the infant in relatively high humidity, to use warm humidified air via the endotracheal tube, and in premature babies, to cover the body surface with an impermeable sheet. However, overhydration is potentially a problem, leading to complications such as pulmonary edema, and fluid restriction may be necessary for treatment of patent ductus arteriosus, renal insufficiency, and chronic lung disease. A recent report highlighted the poor fluid management of many neonates receiving PN.[25] Fluid restriction, or a requirement to administer other fluids in significant volume, can result in the delivery of macronutrients being less than current recommendations. A meta-analysis showed that although a liberal fluid regime decreased weight loss in premature infants on the first days of life, it significantly increased the risk of mortality and the incidence of patent ductus arteriosus and necrotizing enterocolitis (NEC).[26] Thus the recommended fluid intakes of neonates fall between 60 and 80 mL kg^{-1} day^{-1} (for premature infants on the first day of life) and 140 and 170 mL kg^{-1} day^{-1} (for neonates during the stable growth phase).[4] Hence, a one-size-fits-all prescription is inappropriate, and frequent monitoring of weight, urine output, and urea and electrolytes, with reassessment of fluid prescription, should be mandatory in the first weeks of life.

ENERGY SOURCES

Carbohydrates and fat provide the main energy sources in the diet, and this is reflected by their importance as a source of calories in PN. Glucose is a main energy source for body cells and should be the primary energy substrate in PN, covering 60%–70% of nonprotein calories.[4] The amount of glucose that can be infused safely depends on the clinical condition and maturity of the infant, as the ability of neonates to metabolize glucose may be impaired by prematurity and low birth weight. Since (1) pancreatic islet cell function is relatively unresponsive for the first 2 weeks of neonatal life, (2) glycogen stores are limited (Figure 14.1); (3) gluconeogenesis may be impaired; and (4) liver and peripheral tissues are relatively insensitive to insulin, so premature neonates are at risk from both hypoglycemia and hyperglycemia. Glucose infusion should be at least at a rate capable of maintaining blood glucose above 2.6 mmol/L, the current consensus definition of neonatal hypoglycemia.[27] As the rate of endogenous glucose metabolism in neonates is of the order of 5 mg kg^{-1} min^{-1}, this should be considered the lowest infusion rate likely to avoid hypoglycemia.[4] As glucose tolerance increases, the rate of glucose infusion can be increased. However, carbohydrate conversion to fat (lipogenesis) occurs when glucose intake exceeds metabolic needs. The potential risks associated with this process are twofold: accumulation of the newly synthesized fat in the liver and aggravation of respiratory acidosis resulting from increased CO_2 production, although whether these are clinically relevant in PN-fed infants is uncertain. In addition, hyperglycemia in ELBW infants is a risk factor for late-onset sepsis, mortality, and the risk of developing advanced NEC. Hyperglycemia occurs frequently during the course of PN, particularly while the glucose concentration of the infusate is being increased, but most patients will produce adequate endogenous insulin to metabolize the carbohydrate load within hours. Hyperglycemia can also be a sign of impending infection and has also been associated with development of NEC. The treatment of symptomatic hyperglycemia is usually reduction of the infusion rate, but exogenous insulin is sometimes given to ELBW infants with glucose intolerance. A rapid increase in plasma glucose concentration precedes development of NEC, and infants with established NEC have both a high prevalence of hyperglycemia and a worse outcome if hyperglycemic.[28] Hypoglycemia usually results from sudden interruption of an infusion containing a high glucose concentration.

Lipids provide an energy-dense (9 kcal/g of fat), isotonic alternative to glucose as an energy source for PN, which also prevents essential fatty acid deficiency and facilitates provision of fat-soluble vitamins. Combined infusion of glucose and lipids confers metabolic advantages over glucose, because it lowers the metabolic rate and increases the efficiency of energy utilization.[4] There is a close interdependence of carbohydrate and lipid infusion rates on the one hand, and net fat deposition or oxidation on the other (Figure 14.4). When the intake of glucose calories exceeds 18 g kg^{-1} day^{-1} (i.e., REE), net fat oxidation is minimal regardless of fat intake, and net fat synthesis takes place.[29] However, lipid utilization is often low and unpredictable in neonates, and consequently, lipids are usually introduced slowly, especially in premature neonates.[4]

Historically, the first and most commonly used fat emulsions for PN in pediatrics are based on soybean oil, in which the lipid is present as long-chain triglycerides (LCTs). Medium-chain triglycerides (MCTs) can increase

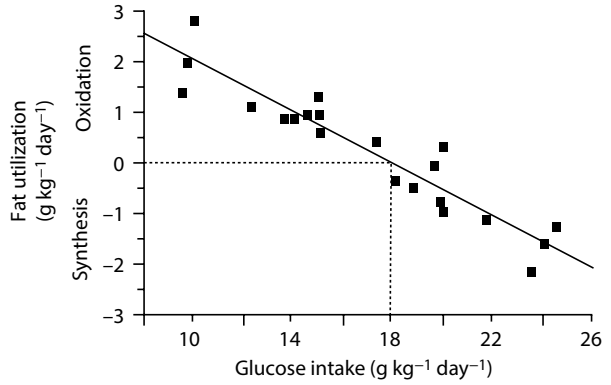

Figure 14.4 Linear relationship between glucose intake and fat utilization ($r = -0.9$; $p < .0001$). Lipogenesis is significant when glucose intake exceeds 18 g kg^{-1} day^{-1}. (From Pierro A et al., Utilisation of intravenous fat in the surgical newborn infant, *Proc Nutr Soc*, 1993, 52, 237A. With permission.)

net fat oxidation without increasing metabolic rate when used to partially replace LCT.[30] MCT/LCT mixtures may improve essential fatty acid status (by protecting essential fatty acids from oxidation). In the last 10 years, several other lipid emulsions have been introduced, based on varying proportions of MCTs, monounsaturated triglycerides (i.e., olive oil), or Ω-3 polyunsaturated triglycerides (i.e., fish oil). These have been utilized in several small-scale studies, in both premature infants and surgical infants. The potential routine use of these novel lipids is complicated by differences in licensing between different geographical areas and by the maximal rate of administration within the license. The main aim of the use of novel lipids, however, is to prevent or treat cholestasis; this will be considered in Section "Hepatic Complications."

High doses of lipid or an accidental rapid infusion of lipid may lead to fat overload syndrome, characterized by an acute febrile illness with jaundice and abnormal coagulation and respiratory problems, so lipids are usually advanced slowly, with close monitoring of triglyceride levels.[4] Peroxidation in stored fat emulsions and the generation of free radicals during intravenous infusion of fat in premature infants have been reported.[31] However, the degree of free radical production is linked to the rate of lipid oxidation, as it has been shown that a reduction in the carbohydrate-to-fat ratio in a PN diet will result in increased oxidation of administered fat and a decrease in free radical–mediated lipid peroxide formation.[32]

AMINO ACIDS

In contrast to healthy adults, who exist in a state of neutral nitrogen balance, infants and children need to be in positive nitrogen balance in order to achieve satisfactory growth and development. Preterm infants who are receiving glucose alone lose protein quickly (at the rate of 1%–2% body protein per day), so they should start to receive at least 1–1.5 g kg^{-1} day^{-1} amino acids parenterally if not receiving enteral nutrition.[33] Infants are efficient at retaining nitrogen and can retain up to 80% of the metabolizable protein intake on both oral and intravenous diets.[33] Protein metabolism, and deposition of body protein for growth, is dependent upon both protein and energy intake, so that above an energy intake of 70 kcal kg^{-1} day^{-1}, the major determinant of nitrogen retention in preterm infants is the amino acid intake.[33] The PN amino acid requirement of term newborn infants is between 2.5 and 3.0 g kg^{-1} day^{-1}, which allows for accretion of body protein.[33] Complications like azotemia, hyperammonemia, and metabolic acidosis have been described in patients receiving high levels of intravenous amino acids[33] but rarely seen with amino acid intake of 2–3 g kg^{-1} day^{-1}.[33] In patients with severe malnutrition or with additional losses (i.e., jejunostomy, ileostomy), protein requirements are higher. The nitrogen source of PN is provided as a mixture of amino acids, and mixtures specifically formulated for neonates are available. However, the ideal amino acid composition for term and preterm infants is uncertain. As well as the amino acids usually considered essential for adult humans, histidine is considered essential for infants, and the following amino acids have all been considered "conditionally essential" for neonates: arginine, cysteine, glutamine, taurine, and tyrosine.

Glutamine is excluded from PN amino acid mixtures because of poor stability, although it can now be added as a dipeptide. Glutamine is important for the immune system and the intestine, as well as being essential as a nitrogen carrier between organs. It has been hypothesized that glutamine supplementation to parenterally fed neonates would decrease the incidence of infection and decrease time to full enteral feeding. One randomized controlled trial (RCT)[34] in surgical infants found that parenteral glutamine supplementation had no significant effect on intestinal permeability or nitrogen balance, although this study was not powered to detect differences in clinical end points such as incidence of sepsis or duration of PN. A large multicenter RCT of glutamine-supplemented PN showed that although glutamine did not decrease the time to full enteral feeds, or the incidence of sepsis over the full period of PN, it did significantly decrease the incidence of sepsis during the period of exclusive parenteral feeding, i.e., before any enteral nutrition was introduced.[35]

MINERALS, VITAMINS, AND TRACE ELEMENTS

Minerals, vitamins, and trace elements are important structurally, as cofactors, or as components of enzymes, and provision of adequate supplies is important for the growing neonate. Fe, Ca, P, and Mg should all be provided in adequate amounts for growth and development but, conversely, can cause problems if provided in excess of needs or if their metabolism is impaired. In addition, administration of adequate amounts can be problematic because of lack of stability in solution or lack of compatibility with other components. Consequently, iron is often only supplemented in longer-term PN,[4] whereas calcium and phosphate supply depends on solubility in PN mixtures.[4] Vitamins and trace elements are particularly important in maintenance of the

body's antioxidant defenses: vitamins C and E; selenium (for glutathione peroxidase); copper, zinc, and manganese (all for superoxide dismutases); chromium; iodine; and molybdenum can all be added to PN. However, for many of these, the precise requirements are not known. Although there is evidence that selenium supplementation may be beneficial, selenium status varies widely geographically, so global recommendations are difficult.[36] It is suggested that if the duration of PN is less than 4 weeks, of the trace elements, only zinc needs to be added.[4] There is little specific evidence for individual vitamin requirements, and the current recommendations are to continue with the available vitamin mixtures, which do not appear to cause toxicity or deficiency in the majority of children.[4]

Complications of PN

INFECTIOUS COMPLICATIONS

In spite of significant improvement in the management of PN, including the introduction of nutrition support teams, infection is still a major problem. More than 50% of surgical infants on PN have at least one suspected episode of sepsis, and around 30% of surgical neonates have at least one positive blood culture.[35] Repeated episodes of sepsis may lead to impaired liver function, critical illness, and removal of central venous catheters. Although catheter-borne infections, which can be reduced by rigorous precautions, such chlorhexidine antisepsis,[37] are important, microbial translocation from the intestine is also a significant source of infection in surgical infants on PN.[38] Infection with enteric microorganisms occurs significantly later than presumed catheter-related infection,[39] supporting the hypothesis that a progressive impairment of host defenses[40] and/or increased intestinal permeability may allow translocation of enteric organisms after an extended period of PN.

MECHANICAL COMPLICATIONS

Mechanical complications related to the intravenous infusion of nutrients are not uncommon. Table 14.1 lists the mechanical complications reported in the literature. Extravasation of PN solution is a common complication of peripheral PN. Unfortunately, even a low osmolarity solution is detrimental for peripheral veins leading to inflammation and extravasation of the solution, which can cause tissue necrosis and infection. Extravasation injury is treated with occlusive dressings or hyaluronidase irrigation, but there is little evidence base for the best treatment in neonates.[41] Intravenous lines may become clogged from thrombus formation, calcium precipitates, or lipid deposition. There is disagreement on the ideal position of central venous lines (CVLs) for PN in infants. Some authors advocate the atrium as the ideal position because this would give less chance of catheter dysfunction, whereas others believe that placement in the superior vena cava would reduce the risk of perforation. The current ESPGHAN/ESPEN recommendations are that the catheter tip should lie outside the atrium,[4] but because complications of either approach are very rare (albeit potentially life threatening), there is a paucity of evidence from RCTs.

Table 14.1 Mechanical complications of parenteral nutrition

Extravasation of parenteral nutrition solution
Blockage of the central venous line
Migration of the central venous line
Breakage of the infusion line
Right atrium thrombosis
Cardiac tamponade (perforation of right atrium or vena cava)

HEPATIC COMPLICATIONS

The hepatobiliary complications related to PN remain serious and often life threatening. The commonest hepatobiliary complication of PN in neonates is cholestasis. The clinical significance of this cholestasis itself is unknown, but if untreated, intestinal failure–associated liver disease (IFALD) may occur, which can result in the need for liver transplantation or can result in death. IFALD has been defined by the British Society of Paediatric Gastroenterology, Hepatology and Nutrition as follows:

- Type 1 early IFALD—persistent elevation of alkaline phosphatase (ALP) and γ-glutamyl transferase (γGT) greater than 1.5 times the upper limit of reference range for at least 6 weeks
- Type 2 established IFALD—elevation of ALP and γGT as in type 1, together with elevation of total bilirubin (>50 μmol/L), with a conjugated fraction of at least 50%
- Type 3 late IFALD—elevated ALP, total bilirubin, and clinical signs of end-stage liver disease

Type 1 is thought to be reversible; type 2 is potentially reversible if enteral feeding is increased, PN reduced, and repeated episodes of catheter-related sepsis are prevented. The incidence of IFALD depends on the length of time on PN, and occurs in up to 50% of infants receiving long-term PN.[42] Although the frequency of this complication seems to be diminishing, this is probably related to the more aggressive transition to enteral feeding rather than to an improvement in the intravenous diet. Various clinical factors are thought to contribute to the development of PN-related cholestasis. These include prematurity, low birth weight, duration of PN, immature enterohepatic circulation, intestinal microflora, septicemia, failure to implement enteral nutrition, short-bowel syndrome due to resection, and number of laparotomies. In addition to the effects of ELBW, and length of time on PN, infants receiving PN for either gastroschisis or jejunal atresia seem to be at particular risk. PN-related cholestasis has a higher incidence in premature infants than in children and adults. This may be due to the immaturity of the biliary secretory system since bile salt pool size, synthesis, and intestinal concentration are low

in premature infants in comparison with full-term infants. PN-related cholestasis and IFALD are diagnoses of exclusion without any specific marker yet available. Therefore, infants with cholestasis (conjugated bilirubin >2.0 mg/dL) who are receiving or have received PN must have an appropriate diagnostic evaluation to exclude other causes of cholestasis, such as bacterial and viral infections, metabolic diseases (e.g., alpha-1-antitrypsin deficiency, tyrosinemia), and congenital anomalies (e.g., Alagille syndrome, biliary atresia, choledocal cyst).

The etiology of PN-related cholestasis remains unclear. Possible causes include the toxicity of components of PN, lack of enteral feeding, continuous nonpulsatile delivery of nutrients and host factors, infection, and sepsis. In particular, the lipid component of PN has been particularly implicated, and many units now use alternative lipid management strategies (see Section "Hepatic Complications"). In addition to lipid management, careful management of these patients under a multidisciplinary team seems to be beneficial.[43] Bowel lengthening procedures, such as the Serial Transverse Enteroplasty (STEP) procedure or longitudinal intestinal lengthening, may help transition to enteral nutrition,[44] whereas in those with advanced liver disease and no prospect of enteral autonomy, transplantation may be considered.

Parenteral nutrition-associated cholestasis (PNAC) and IFALD have been linked to the use of soybean oil, although other factors are thought to be involved. Soybean oil contains mostly Ω-6 fatty acids, which are thought to be proinflammatory compared with Ω-3 fatty acids. In addition, the amount of phytosterols delivered in soybean-based lipid emulsions is relatively high, and phytosterol accumulation has been postulated to cause PNAC/IFALD.[45] Hence, in recent years, there has been great interest in adopting hepatoprotective lipid management strategies in PN of surgical infants and children to either prevent or reverse cholestasis. Several different approaches have been adopted:

1. Decreasing the amount of lipid administered. This can also be achieved by limiting the time on lipid, by lipid-free hours or days. This could potentially result in poor growth due to inadequate calories.
2. Use of Omegaven, a lipid emulsion of 10% fish oil. Fish oil is high in Ω-3 fatty acids and low in phytosterols, so it has been suggested to reverse cholestasis in surgical infants on long-term PN.[46] Use of Omegaven as the only lipid source could, however, potentially result in essential fatty acid deficiency, due to lack of Ω-6 fatty acids, and could also result in poor growth, as the dose of Omegaven is limited to 1.0 g kg^{-1} day^{-1} (compared with 3 g kg^{-1} day^{-1} for soybean-based lipid emulsions).
3. Use of lipid emulsions containing a mixture of LCTs and MCT triglycerides. This has the advantage of increasing fat utilization,[30] ability to use at up to 3 g kg^{-1} day^{-1}, and decreasing the phytosterols and Ω-6 fatty acids administered while ensuring adequate delivery of essential fatty acids.
4. Use of mixed lipid emulsions such as SMOF, which is a mixture of soybean, medium-chain, olive, and fish triglycerides.[47] This has the advantages of lowered amounts of phytosterols and Ω-6 fatty acids, increased fat utilization, delivery of Ω-3 fatty acids, and ability to use at up to 3 g kg^{-1} day^{-1}.

Despite these different approaches, the evidence base supporting any lipid management strategy is lacking due to the paucity of RCTs in this area. It is difficult to design and implement good-quality RCTs, as units already use a variety of alternate lipid management strategies. It is also questionable whether maintaining an infant on a high dose of soybean-based lipid emulsion after the onset of PNAC/IFALD is ethical, so that it is difficult to decide on an appropriate comparison group.

Enteral nutrition

The energy requirement of an infant fed enterally is greater than the intravenous requirement because of the energetic cost of absorption from the gastrointestinal tract and energy lost in the stools (Figure 14.2).

FEEDING ROUTES

Alternative feeding routes where neonates are unable to feed orally include nasogastric or orogastric tubes, nasojejunal tubes, gastrostomy tubes, or jejunostomy tubes. Gastric feeding is generally preferable to intestinal feeding because it allows for a more natural digestive process, i.e., it allows action of salivary and gastric enzymes and the antibacterial action of stomach acid. In addition, gastric feeding is associated with a larger osmotic and volume tolerance and a lower frequency of diarrhea and dumping syndrome. Thus, transpyloric feeds are usually restricted to infants (1) unable to tolerate nasogastric or orogastric feeds; (2) at increased risk of aspiration; or (3) with anatomical contraindications to gastric feeds, such as microgastria. Neonates are obligatory nose breathers, and therefore orogastric feeding may be preferable over nasogastric feeding in preterm infants to avoid upper airway obstruction. However, nasogastric tubes are easier to secure and may involve a lower risk of displacement. In infants requiring gastric tube feeding for extended periods (e.g., more than 6–8 weeks), it is advisable to insert a gastrostomy, to decrease the negative oral stimulation of repeated insertion of nasal or oral tubes. The tube can be inserted using an open, endoscopic, or laparoscopic approach. In infants with significant gastroesophageal reflux, fundoplication with gastrostomy tube or enterostomy tube placement is indicated. In preterm infants with gastroesophageal reflux, enteral feeding can be established via a nasojejunal tube inserted under fluoroscopy. Nasojejunal feeding usually minimizes the episodes of gastroesophageal reflux and its consequences. However, it is common for these tubes to dislocate back in the stomach. Regular analysis of the pH in the aspirate is essential to monitor the correct position of the tube. Feeding jejunostomy tubes can be

inserted through existing gastrostomy or directly into the jejunum via laparotomy or laparoscopy.

SELECTION OF ENTERAL FEEDS

Breast milk is the ideal feed for infants because it has specific anti-infectious activities and aids gastrointestinal maturation and neurological development. When breast milk is not available, chemically defined formulae can be used, which are designed either for term infants or specifically for preterm infants. If malabsorption is present and persists, an appropriate specific formula should be introduced. A soy-based disaccharide-free feed is used when there is disaccharide intolerance resulting in loose stools containing disaccharides. For fat malabsorption, a formula containing MCTs should be used. An elemental (free amino acids) or semielemental (protein hydrolysate containing dipeptides and tripeptides) formula may be indicated when there is severe malabsorption due to short-bowel syndrome or severe mucosal damage as in NEC. Semielemental preparations have the advantage of a lower osmolality, are well absorbed, and have a more palatable taste. Infants recovering from NEC pose a particular problem, as malabsorption may be severe and prolonged. These infants may have had their small bowel resected, in addition to which the remaining bowel may not have healed completely by the time feeds are begun. Feeding may provoke a relapse of the necrotizing enterocolitis, and feeding should therefore be introduced cautiously. However, there is no strong evidence for the time to reintroduce enteral feeds in infants who have had NEC.[48] For persistent severe malabsorption, a modular diet may be necessary. Glucose, amino acid, and MCT preparations are provided separately, beginning with the amino acid solution and adding the glucose and then the fats as tolerated. Minerals, trace elements, and vitamins are also added. These solutions have a high osmolality and, if given too quickly, may precipitate dumping syndrome, with diarrhea, abdominal cramps, and hypoglycemia. It is important, therefore, to start with a dilute solution and increase slowly the concentration and volume of each component. This may take several weeks, and infants will need PN support during this period.

ADMINISTRATION OF ENTERAL FEEDS

Enteral feeds can be administered as boluses, continuous feeds or combination of the two. Bolus feeds are more physiological and are known to stimulate intestinal motility, enterohepatic circulation of bile acids, and gallbladder contraction[49] continuous enteral feeding leads to an enlarged, noncontractile gallbladder in infants. Contraction is observed immediately after resuming bolus enteral feeds, and gallbladder volume returns to baseline after 4 days. Therefore, the mode of feeding has important bearings on the motility of the extrahepatic biliary tree. Bolus feeds mimic or supplement meals and are easier to administer than continuous feeds since a feeding pump is not required. Bolus feeds are usually given over 15–20 minutes and usually every 3 hours; term infants can tolerate a period of 4 hours without feeds before hypoglycemia occurs. In preterm neonates or in neonates soon after surgery, feeds every 2 hours are occasionally given. Where bolus feeds are not tolerated, for example, in the presence of gastroesophageal reflux, continuous feeds should be administered via an infusion pump over 24 hours. This modality of feeding is used in infants with gastroesophageal reflux, delayed gastric emptying, or intestinal malabsorption. Infants with jejunal tubes should receive continuous feeds and not bolus feeds, as the stomach is no longer providing a reservoir.

COMPLICATIONS OF ENTERAL TUBE FEEDING

Enteral tube feeding is associated with fewer complications than parenteral feeding. The complications can be mechanical, including tube blockage, tube displacement or migration, and intestinal perforation. Although infection is less of a risk than with PN, the risk of infected enteral feeds should not be ignored. Other complications involve the gastrointestinal tract. These include gastroesophageal reflux with aspiration pneumonia, dumping syndrome, and diarrhea. Jejunostomy tubes inserted at laparotomy can be also associated with intestinal obstruction. The use of hyperosmolar feeds has been associated with development of necrotizing enterocolitis, dehydration, and rarely, intestinal obstruction due to milk curds.

In surgical infants, enteral feeding often results in vomiting, interruption of feeding, inadequate calorie intake and rarely in necrotizing enterocolitis. In infants with congenital gastrointestinal anomalies, exclusive enteral feeding is commonly precluded for some time after surgery due to large gastric aspirate and intestinal dysmotility. Therefore, appropriate calorie intake is established initially by TPN. Supplementary enteral feeding is introduced when intestinal motility and absorption improve. The percentage of calories given enterally is gradually increased at the expense of intravenous calorie intake. This transition time from TPN to total enteral feeding could be quite long. The presence of significant gastric aspirate often induces clinicians and surgeons not to use the gut for nutrition. However, minimal enteral feeding can be implemented early in these patients even if its nutritional value is questionable. Minimal enteral feeding may be all that is required to enhance some immunological function. Okada et al.[50] have shown that the introduction of small volumes of enteral feed improved the impaired host bactericidal activity against coagulase-negative staphylococci and the abnormal cytokine response observed during TPN. The increase in bactericidal activity against coagulase-negative staphylococci after the addition of small enteral feeds in patients on PN was significantly correlated with the duration of enteral feeding. This implies that stimulation of the gastrointestinal tract may modulate immune function in neonates and prevent bacterial infection.

CONCLUSION AND FUTURE DIRECTIONS

Nutrition of surgical infants and children is complicated by the requirement for growth. Inadequate or unbalanced nutrition may lead to future problems for these children, and we are now able to start to improve nutrition delivery

in order to optimize outcomes as well as survival. Despite advances in nutritional care, such as the multidisciplinary approach, complications such as sepsis and cholestasis remain relatively frequent. Future research should be aimed toward the prevention and treatment of these complications of artificial nutritional support.

Access for enteral nutrition

MICHAEL W. L. GAUDERER AND JULIA ZIMMER

INTRODUCTION

Adequate nutrition in neonates and infants is of major importance to assure optimal health, growth, and development and to support recovery during illness or after surgery. Both enteral and parenteral application routes may be used to provide a patient's caloric requirements. Enteral nutrition can be delivered via an enteral feeding tube (nasogastric/nasoduodenal/nasojejunal, orogastric/oroenteric), a gastrostomy, or a jejunostomy.

Gastrostomy is one of the oldest abdominal operations in continuous use[1] and has played an important role in the management of various surgical conditions of the neonate.[1–6] The procedure was frequently employed for feeding as well as intestinal decompression. In the past decades, there has been remarkable improvement in surgical techniques for gastrostomy placement. Contemporary approaches include techniques with laparotomy (or "open"), such as the Stamm procedure, or minimally invasive techniques, including the percutaneous endoscopic gastrostomy (PEG), the interventional-radiologic guided gastrostomy (IRG), the laparoscopically assisted gastrostomy (LAP), and the laparoscopically assisted percutaneous endoscopic gastrostomy (LA-PEG).[7] Delivery of enteral nutrition may also be postpyloric (duodenal or jejunal) or gastrojejunal.[8] The optimal method of enterostomy must be carefully chosen according to patients' comorbidities and habitus, and caretakers' experience. New techniques such as fluoroscopic guidance or electromagnets permit tube placement in the small bowel without radiographic confirmation.

Depending on the clinical circumstances and the provider's level of comfort, there is a broad array of enterostomy devices available, either traditional (long) tubes or skin-level devices (buttons or balloon type).

Gastrostomies are these days used not only in patients with major congenital anomalies of the gastrointestinal tract and abdominal wall but in an increased number of infants and children without surgical pathology. In most of these, the indication is an inability to swallow, usually secondary to central nervous system impairment. Ironically, often these are patients who have survived because of aggressive neonatal resuscitation and technological advances.

INDICATIONS

In infants, the three main indications are long-term feeding, decompression, or a combination of both modalities. Additional indications include gastric access for esophageal bougienage and administration of medications.

Nasogastric feeding tube versus gastrostomy

Because the newer 5F and 8F infant feeding tubes are highly biocompatible and remain smooth and soft for prolonged periods of time, they are usually well tolerated, even by the smallest premature infants. In general, feeding tubes should be preferred if the expected length of enteral access is up to 1–2 months. Beyond this arbitrary time frame, complications such as naso-otopharyngeal infections and gastroesophageal reflux tend to increase. Gastrostomies should be considered when direct gastric access for feeding or the administration of medication is expected to last more than several months.

Nasogastric decompression tube versus gastrostomy

With careful attention to appropriate intragastric position and regular flushing, nasogastric or orogastric tubes generally decompress more effectively than do gastrostomy tubes. The newer 8F or 10F tubes are well tolerated for up to several weeks. The author's preference when performing gastric decompression lasting up to 3–4 weeks in newborns is a 10- to 20-inch-long (38–51 cm), 8F single-lumen tube. Longer tubes are prone to plugging, thus becoming ineffective. It should be remembered that most commercially available 8F tubes are designed for feeding and have only two

holes. Additional holes of appropriate size should therefore be added. However, care must be taken not to make the holes too big in order to avoid kinking. These 8F tubes should be attached directly or via a short connecting tube to a spill-resistant open container and irrigated regularly. No suction should be applied to single-lumen tubes. Double-lumen (vented) catheters, such as the 10F Replogle tube, originally designed for the aspiration of saliva in patients with esophageal atresia, tend to be much stiffer and are therefore more likely to cause problems. Additionally, if the venting lumen is obstructed and suction is applied, mucosa is sucked into the holes, leading to trauma and rendering the tube ineffective.

Before performing an enteral access in a neonate, several essential issues need to be addressed and clarified to identify the optimal method for enteral nutrition: (1) medical cause for the child`s underlying condition/chance of recovery, (2) length of the anticipated need, (3) anatomical or physiological abnormalities, and (4) what the most efficient workup is and why.

In the author's experience, nasogastric/nasojejunal tubes are mostly only suitable for short-term use (±1–3 months). In case of long-term usage (over ±3 months), gastrostomies are recommendable. If additionally, a stomach bypass is required, a gastrostomy with a jejunal extension tube should be placed or a jejunostomy created.

GASTROSTOMY IN SELECT NEONATAL SURGICAL PATHOLOGY

Esophageal abnormalities

Once considered essential in the management of patients with esophageal atresia, gastrostomies are no longer employed routinely. The analysis of large series demonstrates that esophago-esophagostomy without the use of a gastrostomy is safe[9] and may in fact be beneficial for decreasing the incidence of gastroesophageal reflux.[10] A gastrostomy is indicated in esophageal atresia without fistula, when a difficult repair or a stormy course is anticipated, in staging procedures, and when the child has associated anomalies that may interfere with feeding. The stoma, employed for the decompression or feeding, can also be used to provide access for the management of anastomotic complications such as leakage or strictures.

Duodenal obstruction

Congenital duodenal obstruction is usually associated with proximal duodenal dilatation and atony as well as gastric dilatation. Total parenteral nutrition and nasogastric decompression are generally effective in postoperative management. However, if the need for prolonged gastric decompression is anticipated, a valuable alternative in this setting is the placement of a fine silicone rubber catheter alongside a gastrostomy catheter, across the anastomosis and into the proximal jejunum[1,11] (Figure 15.1). Although these tubes are at times difficult to place and maintain, this simple and time-honored technique can decrease or eliminate the need for parenteral nutrition.

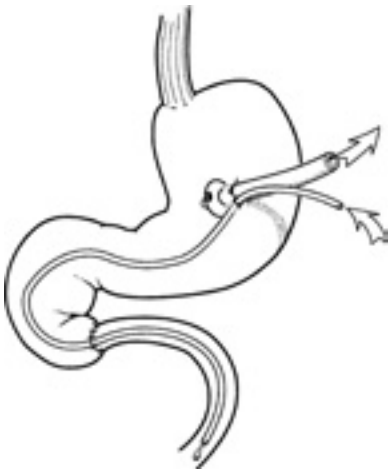

Figure 15.1 Traditional combination gastric decompression and intrajejunal feeding, demonstrated diagrammatically in a newborn with repaired duodenal atresia.

Major abdominal wall defects

Prolonged ileus typically follows the repair of gastroschisis and, occasionally, other major wall defects. Although decompressive gastrostomies are not routinely employed, they can be helpful in patients with gastroschisis and associated atresia, particularly those requiring long-term continuous feeding.

Short-gut syndrome

Infants who have lost over 50% of their small bowel have profound alteration of gastrointestinal physiology. Initial gastric hypersecretion may require prolonged drainage. As the remaining intestine undergoes adaptive changes, continuous enteral feedings become necessary. As this latter process can be fairly lengthy, direct gastric access via gastrostomy is desirable.

Other surgical pathology

In any neonatal or infant condition in which a prolonged ileus or partial luminal occlusion (e.g., recurrent adhesive bowel obstruction, complicated meconium ileus, small bowel Hirschsprung disease) is anticipated or in whom a complex feeding regimen is likely (e.g., those with intestinal lymphangiectasia), a gastrostomy can facilitate management. Gastrostomies are also helpful in some children with extra-abdominal surgical pathologies (Figure 15.2).

"Nonsurgical" pathology

The number of pediatric patients with an inability to swallow referred to a surgeon for the placement of a gastrostomy

Figure 15.2 Ten-month-old child who presented with respiratory distress shortly after birth because of a large left cervical neuroblastoma. The lesion was fully resected on the second day of life. However, the extensive dissection resulted in difficulty swallowing. A PEG was placed at age 4 weeks and swallowing therapy initiated. Normal feeding gradually returned, and a few weeks after this picture was taken, the gastrostomy could be removed. The only residual side effect is a left-sided Horner syndrome.

continues to increase. The main indications in infants are swallowing difficulty secondary to central nervous system lesions as well as other abnormalities of deglutition, feeding supplementation, large-volume medications, and chronic malabsorption syndromes. Because the neurologically impaired children frequently have foregut dysmotility and gastroesophageal reflux in addition to swallowing difficulties, antireflux procedures are at times added to gastrostomies. There are conflicting results about an increased risk of pathologic gastroesophageal reflux after gastrostomy tube placement in neurologically impaired children, resulting in divergent recommendations of simultaneous antireflux surgery.[12,13] A recent Cochrane analysis found that the question of whether to use gastrostomy only or gastrostomy plus fundoplication remains debatable as there are currently no sufficient trials available for comparison.[14]

In general, gastrostomy and gastrojejunostomy procedures in neurologically impaired and chronically ventilator-dependent infants and children have a significant risk of postoperative complications, morbidity, and mortality.[15,16]

ADVANTAGES AND DISADVANTAGES OF GASTROSTOMIES

Direct access to the stomach provides the surgeon with valuable perioperative access for drainage of air or fluids, a reliable long-term source of intermittent or continuous administration of nutrients, or a combination of both. As stated, nasogastric tubes tend to drain better than gastrostomies in the immediate postoperative period. However, a gastrostomy can eliminate the need for long-term nasogastric or orogastric intubation and the complications associated with placement and maintenance of these tubes. Gastrostomies interfere less with oral feedings than do nasogastric tubes, although the newer, smaller catheters are better tolerated. Gastrostomies are preferred over jejunostomies because the latter are less physiological and more prone to mechanical complications.[1]

The disadvantages of gastrostomies in the neonatal period include the need for an operative intervention with or without laparotomy; the observation that the procedure is not always simple, particularly if the child has associated anomalies; and the observation that gastrostomy placement may interfere with gastric emptying and increase the incidence of gastroesophageal reflux.[1,10] It has also been recognized that both nasogastric tubes and gastrostomies may promote gastric colonization with bacteria. Gastrostomies, as well as any other enteral tubes placed in infants, are associated with a long list of potential early and late complications.[1,7,17–21]

The obvious advantage of jejunostomies is the gastric bypass. Gastrojejunal tubes may eliminate the need for antireflux surgery in patients with gastroesophageal reflux.[22]

On the contrary, gastrojejunal tubes are difficult to place and to maintain and need frequent exchanges, usually every 3 months.[8] They provide a less physiologic nutrition as the feedings are usually continuous administered rather than in bolus feedings. Jejunostomies have been found to provide more complications, such as internal hernia and volvulus (the latter particularly in the Roux-en-Y jejunostomies or the "dissociation" technique bypassing the stomach as described by Bianchi). A notable morbidity after gastrojejunal tube placement has been described ranging from persistent reflux to dislodgement and intestinal perforation.[21]

Gastrojejunal and jejunal buttons have the same design as gastrostomy buttons but, additionally, a long distal jejunal tube component.[8] Nowadays, the smallest gastrojejunal button is a 14F button, which is useful in smaller children needing both jejunal access for feedings and gastric decompression.[8] Jejunal buttons (which do not have a gastric lumen) are used in children requiring only jejunal feeding without the need for gastric venting or intragastric access.[8]

TECHNIQUE

There are multiple approaches to construct a gastrostomy. These techniques and their many variations are based on three fundamental principles:

1. Formation of a serosa-lined channel from the anterior gastric wall around a catheter. This catheter is placed in the stomach and exits either parallel to the serosa, as in the Witzel technique, or vertically, as in the Stamm or Kader approaches.[1,23]
2. Construction of a tube or conduit from a full-thickness gastric wall flap, leading to the skin surface. A catheter is then introduced intermittently for feeding. Several different configurations of the gastric wall flap have been described.[1,23]
3. Percutaneous techniques, i.e., without laparotomy, in which the introduced catheter holds the gastric and abdominal walls in apposition, with or without the aid of special fasteners.[1,23]

The Stamm technique, illustrated in this section, is the most widely employed gastrostomy with laparotomy in the neonatal setting, either as an isolated intervention or when employed in conjunction with another intra-abdominal procedure. It can be used in children of any size and even on the smallest stomach (e.g., in newborns with esophageal atresia without fistula). A standard gastrostomy tube or a skin-level device can be placed under local anesthesia, although general anesthesia is preferred because abdominal wall relaxation is required. The procedure is usually short. After the tract is well healed, this stoma is suitable for the passage of dilators or guide wires.

The construction of a gastric wall tube is difficult in very young children. For a variety of reasons, this approach is not appropriate for newborns.

The first of the gastrostomies without laparotomy was PEG, initially developed for high-risk pediatric patients. The diagrams (Figures 15.9 through 15.12) represented follow the initial description of the "pull" PEG.[24] It has been employed in neonates weighing as little as 2.5 kg, usually for the purpose of long-term enteral feeding.[4,25–27] Although there is no need for abdominal wall relaxation, general endotracheal anesthesia is employed in this age group so that the airway is protected from compression during endoscopy. The procedure is very short, and there is no postoperative ileus, no potential for bleeding or wound disruption, and only minimal interference with subsequent interventions on the stomach, such as a fundoplication. The main disadvantage of this and other pure endoscopic techniques is that the virtual space between the stomach and the abdominal wall cannot be visualized. This shortcoming can be overcome by the addition of laparoscopic control.[28,29] Although in the typical PEG, a long tube is initially employed, a primary insertion of a skin-level device is also possible.[30,31]

Several other methods of gastrostomy without laparotomy have been introduced, and most are suitable for newborns. One of these is the percutaneous endoscopic "push" technique, which is performed with the aid of needle-deployed gastric anchors or T-fasteners, and the Seldinger method of guide-wire introduction followed by progressive tract dilatations. A long tube or skin-level gastrostomy device is then inserted.[32] A similar approach is used by interventional radiologists and found to be suitable for even very small stomachs.[33–35]

In the last couple of decades, minimally invasive, laparoscopically aided approaches have been introduced. These are essentially expansions of the aforementioned methods, significantly increasing the choices of gastric access techniques available to surgeons managing infants.[36–38]

Comparative studies regarding efficacy, outcome, and complications of the different techniques are constantly published identifying the LAP procedure as the currently favorable approach.[7,16,17,39–42]

One of the most widely employed laparoscopically aided gastrostomies is illustrated in this section (Figures 15.13 through 15.15). For infants with an abnormal epigastric anatomy, in whom the aforementioned techniques are difficult or impossible to perform, a hybrid procedure employing a mini-laparotomy and the PEG principle was developed.[43]

STAMM GASTROSTOMY

The child is placed on the table with a small roll behind the back. When possible, a nasogastric tube is inserted for decompression and to help identify the stomach, if necessary. A small transverse incision is made over the left upper rectus abdominis muscle (Figure 15.3). This incision should be neither too high, because it would bring the catheter too close to the costal margin, nor too low, avoiding the colon and the small bowel. A short vertical incision is an alternative. However, this approach is less desirable because the linea alba is the thinnest area of the abdominal wall. Bleeders are simply clamped. Fascial layers are incised transversely and the rectus muscle retracted or transected. When identification of the stomach is not immediate, downward traction of the flimsy greater omentum readily allows visualization of the transverse colon and stomach.

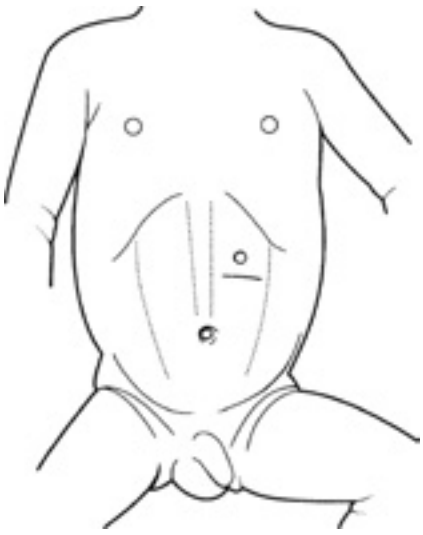

Figure 15.3 Gastrostomy incision and catheter exit site. An alternative is a short vertical midline incision.

The site of gastrotomy placement on the anterior gastric wall is critical in infants. A position midway between the pylorus and the esophagus is chosen (Figure 15.4). The site should be neither too high, because this would interfere with a fundoplication should one be needed in the future, nor too low, because stomas at the level of the antrum are prone to leakage and pyloric obstruction by the catheter. The surgeon must not place the catheter too close to the greater curvature, to avoid the so-called gastric pacemaker and to minimize the potential for gastrocolic fistula.[1]

The anterior gastric wall is lifted with two guy sutures (4-0 silk) at the site of the stoma, ensuring that the posterior wall is not included (Figures 15.4 through 15.7). A concentric purse-string suture (4-0 synthetic, absorbable material) is placed (Figures 15.4 through 15.6). The gastrotomy, at the center of the purse string, is made sharply through the serosa and muscular wall of the stomach.

A small hemostat is introduced to confirm access into the gastric lumen. We prefer a mushroom-type catheter (de Pezzer), sizes 12–14F gauge, for neonates. The mushroom head of the catheter is stretched with a short stylet to allow atraumatic introduction into the stomach (Figure 15.5). The purse string is tied to invert the seromuscular gastric wall around the tube (Figure 15.6). Other suitable catheters are the Malecot or the T-tube, but both have the disadvantage of becoming more easily dislodged. However, a short T-tube is useful if the stomach is very small. It is also our preferred tube for infant jejunostomies. We avoid the Foley or balloon-type catheters because the main lumen is proportionately smaller and the balloon occupies more intragastric space. Long balloon-type catheters, which may rupture, also have a greater propensity for distal migration into the small bowel. Skin-level devices (buttons or balloon type) may be inserted during the operation, instead of the traditional long tubes.[23] The exit site for the catheter should be through the midportion of the rectus muscle about 1–2 cm above or below the laparotomy incision (Figures 15.3 and 15.6 through 15.8). Although some surgeons bring the catheter out by way of the primary abdominal incision, wound complications that may occur in this setting tend to be more complex.[1] Once the exit site is chosen, the anterior gastric wall is secured to the posterior aspect of the anterior abdominal wall with four equidistant sutures or, as illustrated, with a continuous suture of double-ended

Figure 15.4 Gastrotomy site on the anterior gastric wall. The traction guy sutures and the purse-string suture are depicted.

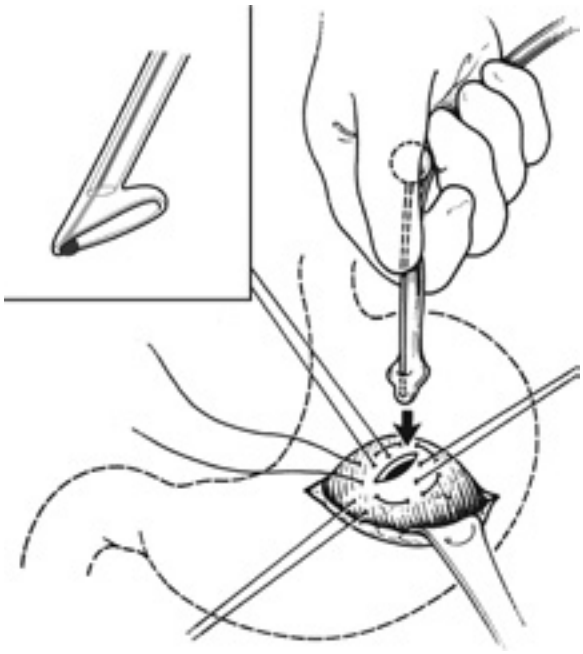

Figure 15.5 Introduction of a de Pezzer catheter using a simple stylet. The inset shows insertion of a PEG-type catheter.[23]

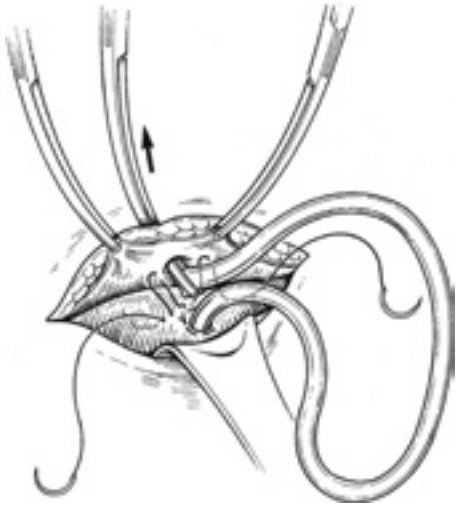

Figure 15.6 The purse-string suture is tied. The continuous monofilament suture, used to anchor the stomach to the anterior abdominal wall, has been partially placed. The catheter is brought out through the counterincision.[23]

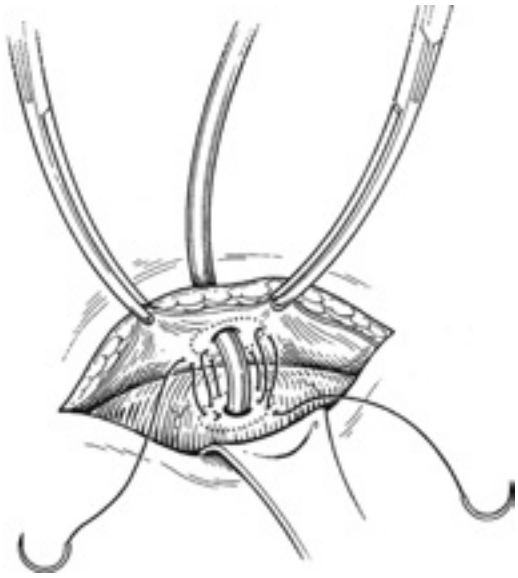

Figure 15.7 The continuous monofilament suture placement is continued anteriorly and then tied. This provides a 360° fixation of the stomach to the anterior abdominal wall with a watertight seal.[23]

Figure 15.8 Completed procedure. The subcuticular closure, adhesive strips, and secured gastrostomy catheter are depicted. The immobilizing sutures are removed after several days, and a small crossbar is placed to prevent distal catheter migration. An alternative is the placement of a "button" or a balloon-type skin-level device, instead of a long tube, at the initial procedure.[23]

4-0 synthetic monofilament thread[27] (Figures 15.6 and 15.7). The catheter position is tested by injecting and aspirating saline. Gentle traction on the catheter assures that its intragastric position is maintained.

The posterior rectus sheath is closed with a running suture of 4-0 absorbable, synthetic material. The anterior rectus sheath is approximated with interrupted sutures of the same material. The subcutaneous layer is closed with a couple of 5-0 or 6-0 synthetic, absorbable sutures. The skin can be approximated with either interrupted or continuous 5-0 or 6-0 subcuticular sutures. Adhesive strips cover the incision (Figure 15.8). The catheter is firmly secured with two sutures of 3-0 or 4-0 synthetic monofilament thread. These sutures are removed after 1 week, and a small crossbar is placed loosely to prevent distal catheter migration. Occlusive dressings are not used after the first couple of postoperative days. Conversion of a long tube to a button can be performed after a firm adherence between gastric and abdominal wall is established.

Percutaneous endoscopic gastrostomy

The PEG technique, as initially described,[24] is applicable to neonates and small infants.[27] The procedure must, however, be done with great precision and endoscopic skill. PEG incorporates four basic elements:

1. Gastroscopic insufflation brings the stomach into apposition to the anterior abdominal wall (Figure 15.9).
2. With the stomach apposed to the abdominal wall, a cannula is introduced percutaneously into the gastric lumen under direct endoscopic guidance (Figure 15.10).
3. This cannula serves as access to introduce a guide wire, which is then withdrawn out of the patient's mouth with the gastroscope (Figure 15.11). A tract is thus established.
4. A PEG catheter with a tapered end is attached to the oral end of the guide wire and pulled in a retrograde fashion until it assumes its final position, keeping the stomach firmly apposed to the abdominal wall (Figure 15.12).

Although there are multiple variations of the original PEG technique[1,24,28–32] and several types of catheters, one must be cautious, because most of these are not suitable for use in infants. We employ a 16F-gauge (or smaller) commercially available silicone rubber pediatric PEG catheter. Larger, stiffer catheters, or those with a stiff, noncollapsible inner retainer, can easily tear the infant's esophagus.

A single dose of an intravenous (i.v.) broad-spectrum antibiotic is administered at the outset. The child remains in the supine position throughout the procedure. The abdomen is cleansed and sterilely draped. Gastroscopy is performed with the smallest pediatric gastroscope available. The scope is inserted and advanced slowly into the stomach, at which point the light is seen through the left-upper-quadrant abdominal wall. With the gastroscope in place, insufflation distends the stomach, apposes it against the anterior abdominal wall, and displaces the colon downward. When the room lights are dimmed, the gastric contour is clearly visible, particularly in small children.

The preferred gastrostomy site is over the midportion of the left rectus muscle, as depicted in the inset of Figure 15.9. Digital pressure is exerted at this site, and this is seen by the endoscopist as a *polypoid lesion* or *mound* on the anterior gastric wall (gastric transillumination and endoscopically

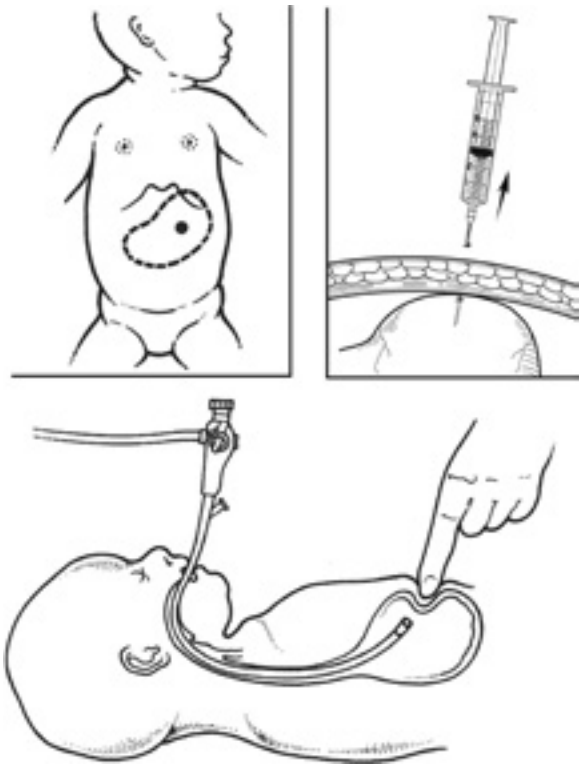

Figure 15.9 Percutaneous endoscopic gastrostomy (PEG). The air insufflated through the endoscope approximates the stomach to the abdominal wall and displaces the colon caudally. Digital pressure is applied to the proposed gastrostomy site, which usually corresponds to the area where transillumination is brightest. Transillumination and clear visualization of an anterior gastric wall indentation are key points. Without these, an open or laparoscopic technique should be employed. Long-lasting local anesthetic is drawn into a syringe and the proposed PEG site injected. The needle is advanced further, and continuous aspirating pressure is applied to the plunger. Air aspiration should only occur when the tip of the needle enters the gastric lumen. (From Gauderer M, Gastrostomy, in Spitz L and Coran AG, editors, *Operative Pediatric Surgery*, 6th ed., London: Hodder Arnold, 2006, 330–55.)

visualized digital indentation of the stomach are the most important factors in safe PEG placement). The endoscopist then places an endoscopic polypectomy snare around this invagination of the anterior gastric wall. Digital pressure is released, and a 0.5–0.7 cm skin incision is made. A hemostat with slightly opened prongs is placed in the incision, recreating and maintaining the intragastric mound (Figure 15.10). Through this incision and through the prongs of the hemostat, a 16-gauge, smoothly tapered, i.v. cannula and needle are thrust through abdominal and gastric walls under endoscopic visualization. This should be performed quickly to avoid displacing the stomach from the abdominal wall. The snare, if properly positioned initially, will be around the advancing cannula. If not, it can be maneuvered to encircle the cannula. A long, monofilament synthetic suture or a plastic-covered steel guide wire is then advanced through

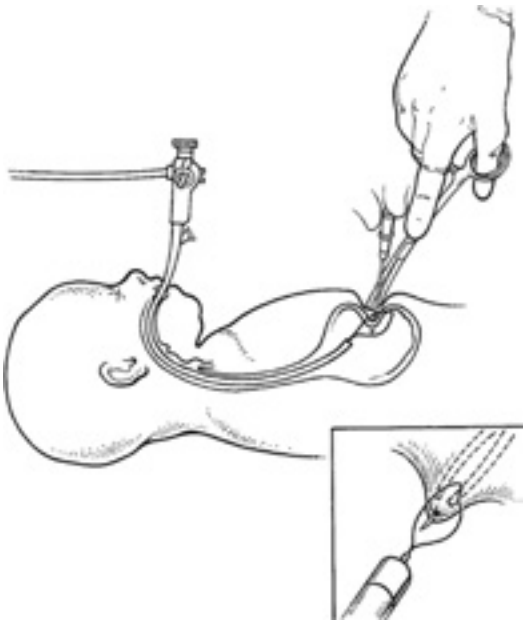

Figure 15.10 A small skin incision is made and a Kelly-type hemostat applied to maintain the intragastric indentation. The endoscopist places the polypectomy snare around the "mound"; the cannula is introduced between the slightly spread prongs of the hemostat and then thrust through the abdominal and gastric walls into the open snare. The snare is partially closed but not tightened around the cannula. (From Gauderer M, Gastrostomy, in Spitz L and Coran AG, editors, *Operative Pediatric Surgery*, 6th ed., London: Hodder Arnold, 2006, 330–55.)

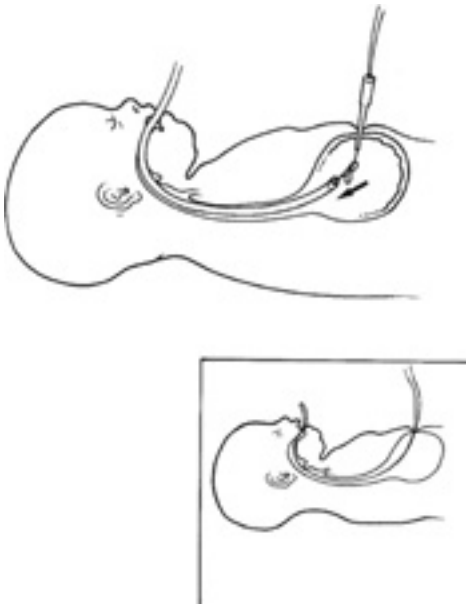

Figure 15.11 The needle is removed and the guide wire inserted. The polypectomy snare grasps the guide and exits it through the mouth. An alternative to the polypectomy snare is an alligator or biopsy forceps. (From Gauderer M, Gastrostomy, in Spitz L and Coran AG, editors, *Operative Pediatric Surgery*, 6th ed., London: Hodder Arnold, 2006, 330–55.)

the cannula and grasped by the snare (Figure 15.11). If there is difficulty with the snare, a biopsy or alligator-type forceps may be used. As the gastroscope and snare are withdrawn, the suture is brought out of the patient's mouth (Figure 15.11, inset). The previously selected PEG catheter is then connected to the suture outside the patient's mouth, and both suture and catheter are coated with a water-soluble lubricant. Traction on the abdominal portion of the suture or guide wire pulls the catheter in a retrograde fashion, through the mouth, esophagus, and stomach, and across the abdominal wall (Figure 15.12). The gastroscope is reintroduced to verify the catheter position under direct vision. While re-endoscopy might theoretically be unnecessary, we believe it adds safety to the procedure.

Traction on the catheter is continued until the inner catheter retainer or "dome" loosely touches the gastric mucosa (Figure 15.12). Markings on the commercially available catheters, or markings added to tubes without marks, are helpful in indicating the final position of the tube. The external crossbar is then placed (Figure 15.12). Excessive pressure by the external crossbar on the abdominal wall will produce pressure necrosis and eventual catheter extrusion, and should be avoided. The tapered catheter end is cut off and a connector attached. Tape is used for temporary catheter immobilization. Although the tube can be used immediately, we have arbitrarily placed it to gravity drainage for the first 24 hours and instituted tube feedings the day after the procedure. The catheter may be converted to a skin-level device by using the external port valve at any time. To replace the PEG catheter with a button or balloon-type skin-level device, we find that it is prudent to wait until firm adhesions between the stomach and abdominal wall are established. This may take 1–3 months or longer.

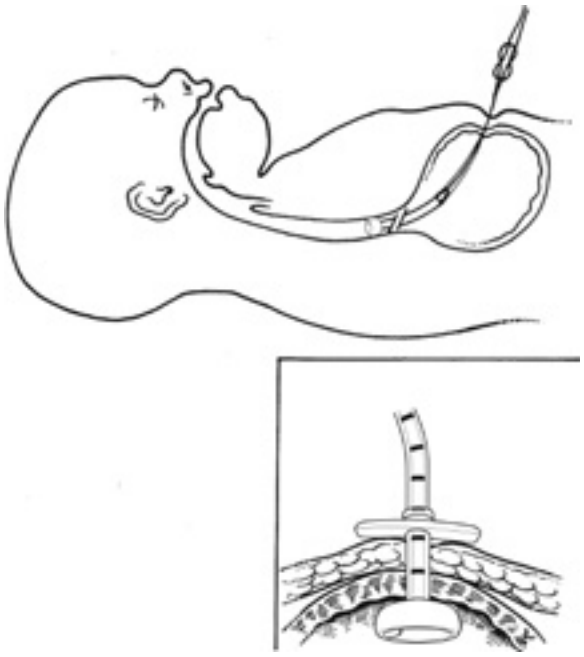

Figure 15.12 The appropriate-size PEG catheter is attached to the oral end of the guide wire and pulled in a retrograde manner through the infant's esophagus and stomach, and then across gastric and abdominal walls. The inset shows the position of the catheter at the end of the procedure. (From Gauderer M, Gastrostomy, in Spitz L and Coran AG, editors, *Operative Pediatric Surgery*, 6th ed., London: Hodder Arnold, 2006, 330–55.)

Minimally invasive gastrostomies

The most recent development in pediatric gastrostomy technique was the introduction of pediatric LAP gastrostomy in the 1990s, combining the advantages of minimally invasive PEG placement with the safety of the open procedure.[7] Hereby, two variations have been reported, a LAP and a LA-PEG.[7,28,44–51]

Laparoscopically assisted gastrostomies

Direct visualization by a laparoscope expands the options for constructing a gastrostomy.[31–36,52] Several approaches have been described. In addition to the videoscopically controlled PEG, the two most common methods are adaptations of the Stamm technique and modifications of the push PEG.[49,51] Our preference is for the latter because in order to place a purse-string suture through the exposed segment of the anterior gastric wall, the trocar site must be sufficiently enlarged. This may predispose the site to leakage. To temporarily anchor the stomach to the abdominal wall, different approaches may be employed, notably T-fasteners and U-stitches. The most suitable site for the gastrostomy is selected in the left upper quadrant and marked. A nasogastric tube is inserted. Pneumoperitoneum is established in the child's size-appropriate manner, a trocar is placed at the umbilicus, and the laparoscope is introduced. A needle is pushed through the previously marked abdominal wall site, and the appropriate relation between the anterior gastric wall and the stoma site established. A small skin incision is made and a 5 mm trocar inserted. A grasper is introduced, and the gastrotomy site on the anterior gastric wall is lifted toward the parietal peritoneum (Figure 15.13). A U-stitch is passed through the abdominal wall, through the anterior gastric wall, and back out through the abdominal wall. A second U-stitch is passed parallel to the first one, 1–2 cm apart (Figure 15.13). The sutures are lifted, maintaining the stomach in contact with the abdominal wall. The grasper and the trocar are removed. The stomach is insufflated with air through the nasogastric tube, and a needle is inserted through the trocar site into the gastric lumen, between the two U-stitches. A Seldinger-type guide wire is passed through the needle into the stomach (Figure 15.14). The tract is dilated over the guide wire to the size required to insert either a Foley-type catheter or a balloon-type skin-level device. These are placed over the same guide wire. Stiffening of the catheter shaft with a thin metallic dilator is helpful. The previously placed U-stitches are tied over the wings of the button (Figure 15.15). If a long tube is placed, a pair of bolsters is employed. Care must be taken to avoid excessive tension.

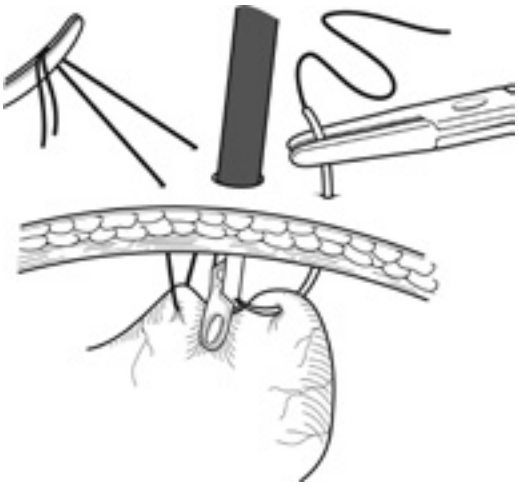

Figure 15.13 Laparoscopically assisted gastrostomy. Following the establishment of pneumoperitoneum and insertion of a trocar at the gastrostomy site, a grasper is introduced, and the appropriate portion of the anterior gastric wall is lifted. Two sutures are placed in the depicted manner. (From Gauderer M, Gastrostomy, in Spitz L and Coran AG, editors, *Operative Pediatric Surgery*, 6th ed., London: Hodder Arnold, 2006, 330–55.)

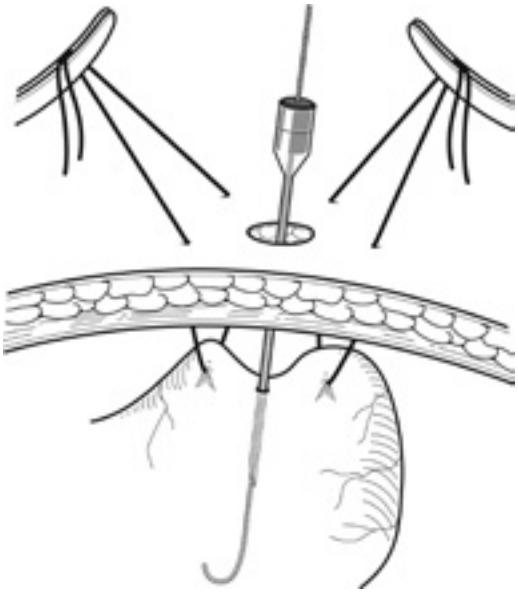

Figure 15.14 The stomach is insufflated with air through the nasogastric tube, and a needle is inserted through the trocar site into the gastric lumen, between the two U-stitches. A Seldinger-type guide wire is passed through the needle into the stomach. The tract is dilated over the guide wire to the size required to insert either a Foley-type catheter, a balloon-type skin-level device, or another low-profile access device. These are placed over the same guide wire. (From Gauderer M, Gastrostomy, in Spitz L and Coran AG, editors, *Operative Pediatric Surgery*, 6th ed., London: Hodder Arnold, 2006, 330–55.)

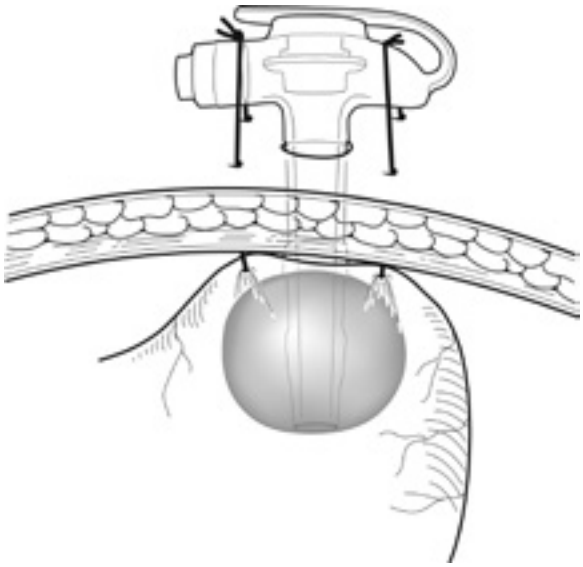

Figure 15.15 A balloon-type "button" has been placed. The previously placed U-stitches are tied over the "wings" of the skin-level device. (From Gauderer M, Gastrostomy, in Spitz L and Coran AG, editors, *Operative Pediatric Surgery*, 6th ed., London: Hodder Arnold, 2006, 330–55.)

In the past decades, various working groups have variated and improved the LAP procedure, such as one- or two-trocar techniques or microinvasive strategies[42,44,45,50,53]: One-trocar aided gastrostomy has been shown to be feasible by Kawahara et al.[53] Patel and colleagues[45] developed a modified two-port LAP approach using the Seldinger technique with serial dilatation and tube insertion through a peel-away sheath for children with epidermolysis bullosa.

Turial et al.[50] introduced microlaparoscopic-assisted gastrostomy where a 1.7 or 1.9 mm 0- degree camera is inserted through the umbilicus and a 5 mm port is placed over the stomach at the designated site for the tube placement. The stomach is grasped and exteriorized and a gastrostomy opened, followed by a balloon gastrostomy tube placement.

Stitch technique has also been modified by several authors, e.g., replacement of single U-stitches with a continuous double U-stitch suture,[54] subcutaneous placement of absorbable stay sutures,[55] or laparoscopically placed sutures to secure the stomach to the abdominal wall.[56]

Laparoscopic-assisted percutaneous endoscopic approach

To achieve optimal visualization of the operation sites, LAP gastrostomy placement has been combined with the traditional PEG technique. Here as well, various working groups developed and adapted different operating strategies during the course of time.[49,57–60]

The gastroscope is placed within the stomach, and a port is introduced trough the umbilicus. Pneumoperitoneum is

achieved depending on the patient's age. A camera is introduced into the peritoneal cavity, the ideal gastrostomy site, and a skin incision is made for the abdominal wall exit site. Under direct visualization by both gastroscope and laparoscope, T-fastener pexy sutures can be placed from the proposed gastrostomy site on the abdominal wall into the insufflated stomach. The next step is a needle placement at the center of the sutures from the abdominal incision into the stomach through which a guide wire is passed. Under visualization, an appropriate-size dilator–peel-away sheath is passed over this guide wire into the stomach followed by removal of both guide wire and dilator (Seldinger technique). Then an appropriate-size button is introduced through the peel-away sheath. The latter is removed, and the balloon is inflated with water (usually 3–5 mL). The pexy sutures are pulled outside and tied subcutaneously, leaving the gastrostomy button in the center of the sutures at the proposed gastrostomy button site. Inspection with both gastroscope and laparoscope ensures a proper gastrostomy tube placement. Gastroscope, camera, and port are removed, and the port site is closed with a dissolvable stitch after removal of the port and desufflation of the peritoneal cavity (technique adapted from Livingston et al.[49] and Hassan and Pimpalwar[59]).

In variation, two transabdominal incisions can be made for laparoscopic working instruments besides the umbilical port, and only three sutures may be placed around a proposed gastrostomy site.[60]

Other authors suggest to insert two U-stitches on a large needle through skin and abdominal wall into the gastric lumen and lead them back out again under endoscopic vision.[57] The needle and guide wire are placed between these two stitches, and subsequently, a dilatator and button are introduced. The U-sutures are then tied down over cotton bolsters to appose the stomach to the abdominal wall.[57]

SELECT COMPLICATIONS OF GASTROSTOMIES

Although frequently considered a "simple" procedure and often delegated to a junior member of the surgical team, a gastrostomy has considerable potential for early and late morbidity, particularly among neonates.

Complications related to operative technique

SEPARATION OF STOMACH FROM ABDOMINAL WALL

This serious mishap most commonly occurs after early gastrostomy tube reinsertion, before a firm adhesion between gastric and abdominal walls has occurred. However, it can also occur at any time thereafter. During the attempt to replace a dislodged catheter, the stomach is pushed away from the abdominal wall; that displacement leads to a partial or complete separation of the stoma. If recognition of the problem is delayed, severe peritonitis and death may result.[1–3,6,20,26] To avoid this and other mechanical problems, the stomach must be firmly anchored to the anterior abdominal wall and the catheter well secured to the skin, particularly with the open, Stamm-type techniques. In the event of early removal or dislodgement of the tube, the tract can be gently probed and a thin Foley catheter inserted. This must be followed by injection of a radio-opaque contrast material under fluoroscopy to assure an intragastric position of the tube and absence of intraperitoneal leakage. If there is any question about the position of the catheter, prompt exploration is necessary.

WOUND SEPARATION, DEHISCENCE, AND VENTRAL HERNIA

The aforementioned are usually the result of technical problems and carry high morbidity and mortality rates.[1,3,6] Leakage from an enlarged incision can be life threatening.[6] Such mishaps can be minimized by the use of appropriate, small incisions and by bringing the tube out through a counterincision. These complications will not occur after a PEG, or a LAP gastrostomy, because there is no laparotomy.

HEMORRHAGE

Major bleeding is described in pediatric series[3,5] and is usually related to inadequate hemostasis at the time of catheter insertion. Gentle traction on the catheter can control the bleeding, but reoperation may become necessary.[20]

INFECTION

This complication can occur with any type of gastrostomy.[1,5,6,20,26,61] Although usually limited to the skin and subcutaneous tissue, it can lead to full-thickness abdominal wall loss. Infections are less common following PEG placement or LAP gastrostomy and can usually be avoided through the use of prophylactic antibiotic administration and a skin incision only slightly larger than the diameter of the tube.

INJURY TO THE POSTERIOR WALL OF THE STOMACH

The posterior gastric wall can be damaged or perforated not only during the initial procedure[62] but also later during catheter change.[1] Once the tube is introduced, air or saline should be injected to test the tube's position and function.

INJURY TO OTHER ORGANS

During open procedures, damage to the liver and spleen can occur through the improper use of retractors or other instruments. The distended colon may be mistaken for the stomach, particularly in patients with intra-abdominal adhesions in whom mobility of intestinal loops is limited.

GASTROCOLIC FISTULA

Although it can occur with any gastrostomy, this complication is more likely with the percutaneous endoscopic techniques.[1] With proper technique, however, this problem should be rare. During the PEG procedure, the importance of appropriate gastric insufflation with downward colonic displacement, transillumination, and the indentation on the anterior abdominal wall cannot be overemphasized. On the other hand, overinflation must be avoided because it can distort the local anatomy, including the position of the colon. Additionally, air-filled small bowel loops will displace the colon cranially and move it between the stomach and the abdominal wall.

Complications related to care of stoma

SKIN IRRITATION AND MONILIASIS

Next to granulation tissue, these are the most frequent problems encountered. Usually related to leakage, and compounded by occlusive dressings, irritation is best prevented by avoiding any occlusive devices, including nipples, tape, or gauze pads.[1] The site should be kept open and dry at all times. Ointments and other solutions, except for the treatment of moniliasis, should be avoided. Catheters, if kept long, can be immobilized with a small external crossbar.

TUBE PLUGGING

Catheters must be flushed with water after each feeding to prevent blockage. In neonates the amount should be small and added to the fluid intake.

ADMINISTRATION OF IMPROPER FEEDINGS

Careful and slow administration of the appropriate nutrient prevents metabolic abnormalities as well as diarrhea and excessive reflux.

DELAY IN THE REINTRODUCTION OF A DISLODGED CATHETER

Accidental dislodgement of long gastrostomy catheter is fairly common. The catheter must be replaced before the tract closes, which can be in a few hours unless it is well matured and epithelium lined. Careful dilation of the tract is usually successful.

In gastrostomy skin-level devices with jejunal extension, dislodgment of the tube from the jejunum back into the stomach can occur, which usually requires radiologic (fluoroscopy) or endoscopic guided repositioning.

TRAUMA DURING REINSERTION OF CATHETER

Improper catheter reintroduction can lead to damage to the pancreas, liver, or spleen, particularly if long stylets or other traumatic instruments are used to elongate a mushroom-type tip. Small children are more prone to this complication, given the short distance of these organs from the abdominal wall. Gentle insertion and aiming toward the gastric cardia or fundus is the method least likely to project injury.

Complications related to catheters

GRANULATION TISSUE

This is by far the most frequent problem associated with gastrostomies. Usually, granulation tissue formation is mild, and a few applications of silver nitrate are curative. If this condition is neglected, however, granulation tissue will predispose to leakage, bleeding, and chronic discharge. With excessive growth, excision and cauterization become necessary. Granulation tissue formation will cease once epithelialization of the tract has occurred. We have found that a cream combining an antifungal and a steroid preparation helps to minimize the formation of this abnormal tissue.

LEAKAGE

Severe continuous leakage is uncommon in properly constructed gastrostomies.[1,6] However, severe widening of the stoma can lead to skin excoriation, dislodgment of the tube, metabolic imbalance, and even death.[1,6] the main cause of leakage in most children is enlargement of the stoma by the pivoting motion of the gastrostomy tube, which is often too large or too stiff.[1] Catheters brought through the incision or the thinner midline are more prone to this problem. Management of leakage begins with control of granulation tissue and placement of a smaller, softer catheter to avoid pivoting motion. A variety of other methods have been tried with varying degrees of success.[1] In extreme cases, reoperation or stoma relocation becomes necessary.

INTERNAL MIGRATION

Distal migration of a long catheter producing high intestinal obstruction is a well-known problem.[1,6] It can occur with any gastric tube but is particularly common with long, balloon-type catheters.

EXTERNAL MIGRATION

Overzealous approximation of external immobilizing devices, such as the bumper, can lead to embedding of the inner crossbar of the PEG catheter, mushroom tip, or balloon in the gastric and abdominal wall.[1] The resulting so-called buried bumper syndrome (BBS) is defined as the migration of the internal fixation device (bumper) of the PEG tube alongside the stoma tract out of the stomach over a variable distance with complete or partial loss of tract patency between the stomach and the PEG tube tip.[16,63] The bumper can end up anywhere between the stomach mucosa and the skin surface, which is typical for rigid or semirigid internal immobilization devices.[63]

The usual presentations are malfunction with limited flow, leakage, lack of to-and-fro motion of the catheter, and the formation of an abscess. The catheter should be removed and replaced. This problem can be avoided by giving the catheter enough "play," i.e., a little to-and-fro motion.

However, BBS is quite rare in neonates due to their thin abdominal wall. Since the development of skin-level devices such as buttons, problems with BBS decreased markedly.

PERFORATION OF ESOPHAGUS AND SMALL BOWEL

The balloon of a Foley-type catheter can be accidentally inflated in the esophagus[64] or small bowel,[65] leading to wall disruption.

PERSISTENT GASTROCUTANEOUS FISTULA

In the longstanding gastrostomy, an epithelium-lined channel will form. Although most stomas close spontaneously after a few days, excision of the tract with simple closure is indicated if drainage persists after several weeks.[1]

Prevention

As outlined in the previous segment, a long list of complications is recorded, which can be particularly dangerous in the newborn age group. Most of the common gastrostomy care–related problems can be prevented with meticulous attention to detail during placement and subsequent follow-up.[26] The use of skin-level devices such as the original gastrostomy button,[1] the balloon-type versions, or the externally placed port valve has dramatically decreased the most common problems associated with older, long tubes. Many techniques, whether open, endoscopic, or laparoscopically aided, now permit the initial placement of one of these well-tolerated skin-level devices (Figures 15.16 and 15.17). Jejunostomy and gastrojejunal tubes are even more prone to complications, as outlined in the previous segment. A gastrojejunal button that is too big may cause pyloric obstruction in smaller children.[8]

Figure 15.16 Completed percutaneous endoscopic gastrostomy and tracheostomy in a 4-month-old child, weighing 3.5 kg, with poor swallowing and severe bronchopulmonary dysplasia. The child was born prematurely at 29 weeks' gestation and was hospitalized following an eventful neonatal course. Sutures are not used after the PEG, and the catheter is connected to a small clear plastic trap. After 24 hours, the external crossbar is checked and loosened, if necessary, to accommodate for wound edema. Feedings are then started. Notice the tracheal traction sutures used as safety measures with the child's tracheostomy and the scar of a previously repaired inguinal hernia. (From Ferguson DR et al., Placement of a feeding button ("one-step button") as the initial procedure, *Am J Gastroenterol*, 1993;88:501–04.)

Figure 15.17 Two former premature infants with complex neonatal courses. Both receive supplemental feedings and medication via the gastrostomy. The child on the left has a balloon-type skin-level device, and the one on the right has an original, low-profile gastrostomy button.

CONCLUSION

Although gastrostomy is a basic and fairly simple procedure, the surgeon must carefully consider the advantages versus disadvantages when using it in conjunction with another major intervention in the newborn. So far, jejunostomies play only a minor role for nutritional access in neonates and infants. If the gastrostomy is used for long-term enteral feeding, careful consideration must be given not only to the often difficult ethical problems encountered in some neonatal patients, but also to the duration of these enteral feedings, potential complications, and the problem of gastroesophageal reflux. These children benefit from a team approach, including the neonatologist, pediatric surgeon, pediatric gastroenterologist, primary nurse, and nutritionist. It is also paramount that the parents or caregivers be an integral part of the decision-making process at the different stages of management. Long-term follow-up is essential, and its importance cannot be overemphasized. Whether the gastrostomy is placed as an adjunct or for the prime purpose of feeding, every effort should be directed toward resuming oral feeding whenever possible.

Stomas of small and large intestine

ANDREA BISCHOFF AND ALBERTO PEÑA

INTRODUCTION

The creation of an intestinal stoma is an operation frequently performed in pediatric surgery, especially for cases of anorectal malformations and necrotizing enterocolitis, and frequently indicated for Hirschsprung disease. Its purpose is to divert the fecal stream for different reasons. The diversion can be total (separated stomas) or partial (loop colostomies).

In the management of anorectal malformations, the goal of a colostomy is slightly different. The colostomy must decompress the gastrointestinal tract but must be totally diverting to avoid fecal contamination of the urinary tract, since over 85% of the patients with an anorectal malformation have a distal communication with the urogenital tract. In order to achieve these goals, we recommend a colostomy located in the left lower quadrant of the abdominal wall, with separated stomas (Figure 16.1). The proximal stoma is created using the lowest portion of the descending colon, taking advantage of its attachments to the posterior and lateral abdominal wall, which helps to avoid prolapse. The colostomy must be created leaving enough distal colon (sigmoid) for the future pull-through. The proximal stoma should be matured and located in the center of a triangle formed by the last left rib, the umbilicus, and the iliac crest, in order to allow a colostomy bag to be adapted to a flat surface of the abdomen. The distal stoma must be separated enough from the proximal one to be sure that it is possible to adapt a stoma bag onto it, without overlying the mucous fistula. In addition, the mucous fistula should be made very small and flat (Figures 16.1 and 16.2), since it is only used for irrigation and injection of contrast material to define the anatomy of the malformation prior to the main repair.[1] This maneuver helps to avoid prolapse of this distal mobile segment of the sigmoid.

An important step during the creation of a colostomy consists in irrigating, with saline solution, the distal portion of the bowel until it is completely clean of meconium. Leaving meconium distally can result in infection and contamination of the urinary tract.

Due to the fact that we work at a pediatric colorectal referral center, we frequently receive patients born with an anorectal malformation who had a colostomy done elsewhere, at birth, and were referred to us thereafter for definitive reconstruction.[2] Because of this, we have been exposed to a great variety of colostomies. This has allowed us to learn about the advantages and disadvantages of the different types, the most common complications, and how to deal with them, and to describe strategies to avoid them.

MOST COMMON ERRORS

Stoma mislocation

This type of error may occur in different ways:

1. *Proximal and distal stomas placed too close to each other.* When this happens, the colostomy bag covers both stomas and allows for passage of stool from the proximal to the distal colon. As a consequence, some patients suffer from recurrent urinary tract infections. Also, the stoma bag may be difficult to adapt to the skin. The management of this problem can include (1) performing the main repair earlier than anticipated and (2) revising the stomas by separating them.

   The decision will depend on the specific clinical circumstances. If the surgeon decides to perform the main repair earlier than anticipated, he/she must keep in mind that there is a possibility that the patient may pass stool through a reconstructed area, which may increase the risk of infection. To avoid that, the surgeon may (a) clean the entire gastrointestinal tract preoperatively and then keep the patient fasting for a period of time (about a week) receiving parenteral nutrition or (b) use a purse-string, long-term absorbable suture in the distal

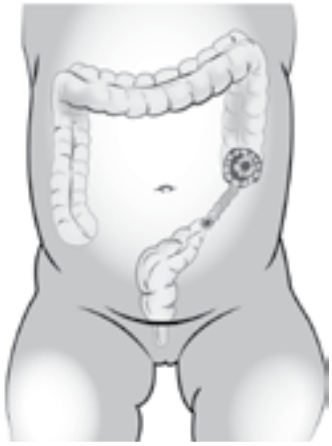

Figure 16.1 Descending colostomy, with mucous fistula.

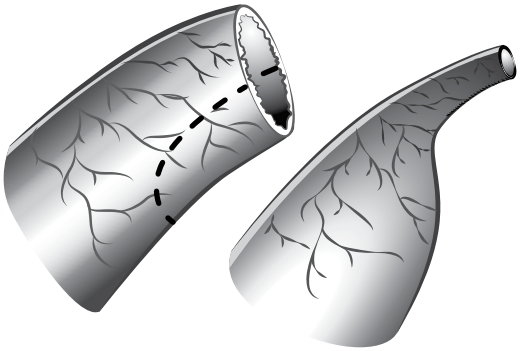

Figure 16.2 Distal stoma made tiny and flat to help avoid prolapse.

stoma to occlude its lumen temporarily and avoid the distal passage of fecal material postoperatively.

2. *Colostomy created too distal in the sigmoid, not allowing enough distal length for the rectal pull-through* (Figure 16.3). In this case the surgeon has several options. The first is to perform the pull-through, taking down the distal stoma (mucous fistula) and closing it as a Hartman pouch. Sometimes the piece of bowel is so short that it will make a very difficult future colostomy closure, since the anastomosis will have to be done deep down in the pelvis, behind the bladder. The second option is to close the colostomy at the time of the main repair and then pull down the rectum, leaving the patient without the benefit of a protective colostomy. For that, we recommend cleaning the entire gastrointestinal tract preoperatively and leaving the patient fasting 7–10 days, receiving parenteral nutrition. The third option is to close the colostomy, pull the rectum down, and create a proximal new colostomy to divert the stool and protect the perineum.

   It is vital to try to save the distal rectum, and avoid discarding it and pulling through the proximal stoma. This is particularly important in patients with anorectal malformation. The resection of the rectum means the removal of the natural human fecal reservoir; this results in having frequent bowel movements and sometimes, tendency to diarrhea. All this seriously interferes with the toilet training process; patients with potential for bowel control will suffer from fecal incontinence.

3. *Inverted stomas* (Figure 16.4). The functional (proximal stoma) is inadvertently placed in the location of the mucous fistula and vice versa. An additional problem occurs because the surgeon mistakenly tapers the proximal bowel, assuming that it is the mucous fistula, which may provoke an obstruction. This complication may require a reoperation. Furthermore, since the stomas are inverted, the mucous fistula (distal stoma) is erroneously placed in the location of the proximal stoma, (high in the abdomen), which will interfere with the pull-through.

4. *Sigmoid colostomy in the upper abdomen* (Figure 16.5). In this case the surgeon planned to do a transverse colostomy. Consequently, he/she made an incision in the upper abdomen, found a piece of colon and brought it out as a colostomy believing it was the transverse colon. Instead a sigmoidostomy was inadvertently opened in

Figure 16.3 Colostomy placed too distal with not enough distal bowel for the pull-through.

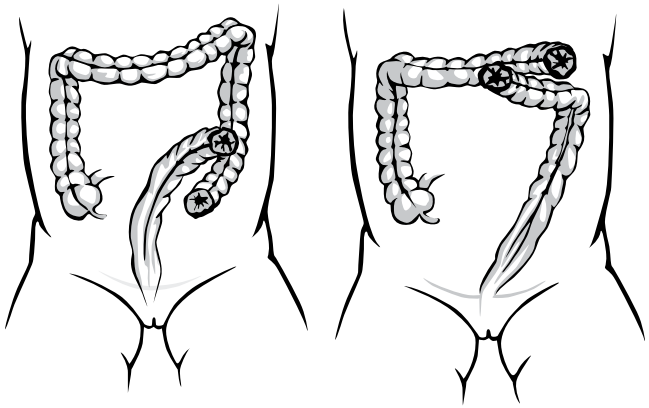

Figure 16.4 Inverted stomas.

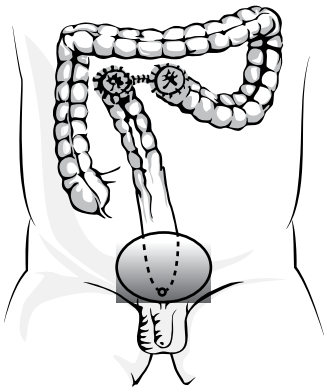

Figure 16.5 Right upper sigmoidostomy instead of a right transverse colostomy.

the upper abdomen, which then can interfere with the pull-through. When opening a transverse colostomy, the surgeon must remember that newborns have a very dilated and mobile sigmoid colon that can reach the diaphragm. When this error is detected, prior to the pull-through, the colostomy must be moved to the lower abdomen.

The diagnosis of a mislocated colostomy is best determined by a distal colostogram, which is a routine study done prior to the main repair of an anorectal malformation.

Prolapse

The second most common complication observed in colostomies is prolapse. This can be a serious complication that can result in intestinal loss due to ischemia. We believe that most prolapses can be avoided by creating the colostomy adjacent to a fixed portion of the colon. If the colostomy has to be created in a mobile portion of the bowel, we recommend that it be fixed to the anterior abdominal wall, approximately 6–7 cm proximal to the stoma. In Figure 16.6, one can identify the mobile and fixed portions of a normally rotated colon, and understand the segments that are prone to prolapse and will need fixation to the abdominal wall.

When a patient presents to us with significant prolapse, we recommend a surgical repair. Our technique consists in inserting a large amount of packing gauze soaked in povidone–iodine in the prolapsed bowel, gently reducing the prolapse. Then the abdomen is palpated, feeling for the mass that corresponds to the packing gauze inside the bowel, naturally oriented inside the abdomen. A transverse incision is then made on top of the palpated mass, usually about 5 cm away from the stoma, opening skin, subcutaneous tissue, muscle, aponeurosis, and peritoneum. The bowel full of gauze is easily identified. The peritoneum and aponeurosis are closed with interrupted long-term absorbable stitches, including in each stitch a bite of the bowel wall (without taking the packing gauze), securing it to the abdominal wall, which helps to avoid future prolapse. When using this technique, the stoma does not need to be touched.

Stenosis

This happens more often than doctors suspect, and patients may suffer from obstructive symptoms. When opening a stoma, we specifically recommend creating an adequate space to pass through the functional bowel, without being compressed by the fascia. In other words, we specifically avoid creating stomas through a simple stab wound. We resect a circle of skin, as well as a circle of aponeurosis, muscle, and peritoneum. Most cases of stoma stenosis do not respond to dilations and need reoperation.

Retraction

This complication is a result of a technical mistake and therefore a preventable problem. An acute, early retraction can be a surgical emergency. A late retraction may represent a serious difficulty in managing the stoma, since it will be hard to adapt the stoma bag. Reoperation with mobilization of the stoma higher above the skin surface is required.

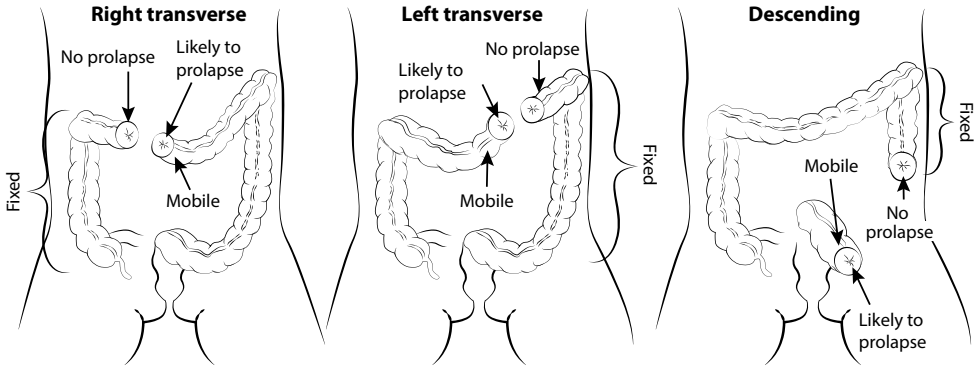

Figure 16.6 Right transverse colostomy (distal stoma likely to prolapse), left transverse colostomy (proximal stoma likely to prolapse), descending colostomy (distal stoma likely to prolapse).

STOMAS IN CLOACAL EXSTROPHY

A special comment should be made about stomas in patients born with cloacal exstrophy.[3,4] A common misconception is that these patients have a short and therefore useless colon. As a consequence, many surgeons perform an ileostomy at birth, leaving the colon distally attached to the urinary tract or simply discarding it. However, the colon is extremely valuable for these patients, allowing them to form solid stool and making them future candidates for a colonic pull-through.[4] It is very important to incorporate every single piece of colon into the fecal stream, regardless of how small it is. In other words, these patients must receive a real end colostomy. Over time, those small pieces of bowel grow considerably. Another advantage of incorporating colon in the fecal stream is that those patients become easier to manage than a patient having an ileostomy. We have reoperated on patients initially managed in other institutions, in order to incorporate a piece of colon that was left distally defunctionalized. We call that procedure "rescue operation," and it consists in closing the ileostomy, separating the colon from the urinary tract, and creating a real end colostomy.[5]

Leaving a piece of colon distally attached to the urinary tract may produce severe hyperchloremic acidosis as a consequence of absorption of urine.

ILEOSTOMIES

Another special comment should be made about ileostomies, a common procedure done for total colonic aganglionosis[6] and necrotizing enterocolitis. Since by definition, the ileostomy will always be made in a mobile portion of the intestine, the risk of prolapse is very high; therefore, we recommend fixing the bowel to the anterior abdominal wall, approximately 6–7 cm proximal to the stoma. All the other complications described for colostomy apply for ileostomies. Other particular issues associated with ileostomy include managing the possible electrolyte disturbances. Patients need to maintain good hydration, and parents need to be keen observers of stoma output. These patients tend to have significant sodium losses and may need oral sodium supplementation.

COLOSTOMY CLOSURE

Colostomy closure in the pediatric population is also associated with a high morbidity rate due to potential avoidable complications such as anastomotic dehiscence, stricture, wound infection, bleeding, and death.[7–23]

Our perioperative protocol for colostomy closure[23] consists in (1) admission on the day before surgery; (2) clear liquids by mouth; (3) repeat proximal stoma irrigations with saline solution 24 hours prior to the operation; (4) administration of intravenous (IV) antibiotics during anesthesia induction and continued for 48 hours; and (5) meticulous surgical technique that includes the following:

1. Packing of the proximal stoma
2. Plastic drape to immobilize the surgical field
3. Multiple silk sutures in the mucocutaneous junction of the stomas to provide uniform traction that allows the surgeon to identify the correct dissection plane, remaining as close as possible to the bowel wall (Figure 16.7)
4. Careful hemostasis
5. Emphasis in avoiding contamination
6. Cleaning the edge of the stomas to allow a precise anastomosis (Figure 16.8)
7. A two-layer, end-to-end anastomosis with separated long-term 6-0 absorbable sutures (Figure 16.9)
8. Generous irrigation of the peritoneal cavity and subsequent layers of the abdominal wall, with saline solution
9. Closure by layers to avoid dead spaces and hematomas
10. Wound coverage with Dermabond (Figure 16.10)

In postoperative care, no nasogastric tubes are used, and the patients receive clear fluids on the first postoperative day, if they are not distended or nauseated. Most of the patients can be discharged home on the second or third day following the operation.

When the size discrepancy between proximal and distal stoma is more than 5:1, with the distal stoma diameter being less than 1 cm, the colostomy closure can present a serious

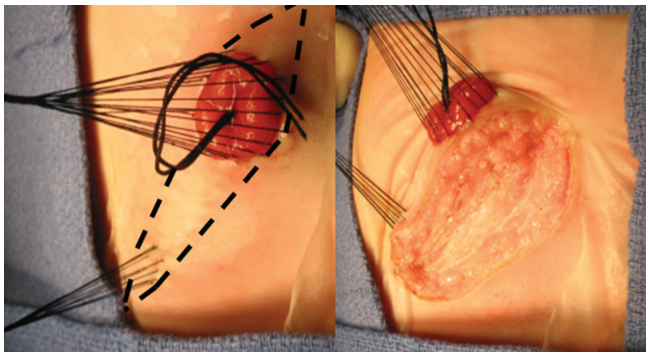

Figure 16.7 Multiple silk sutures in the mucocutaneous junction, which allow for a uniform traction. The dotted line shows the elliptical incision. The opening is performed layer by layer.

technical challenge; for that, we use the same technique that we have used for cases of colonic atresia. The technique consists in performing an end-to-side anastomosis plus a window-type stoma created about 5–10 cm proximal to the anastomosis (Figure 16.11). During the first few postoperative days, one can see a large fecal output through the window; eventually, the output decreases, and the amount of stool passing through the downstream bowel increases, until the window closes up, the anastomosis is efficient, and the microcolon gradually grows.

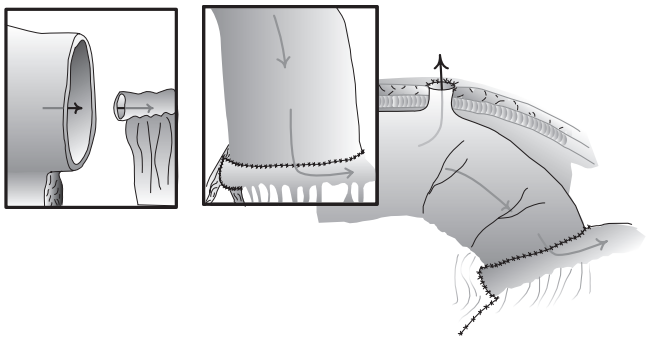

Figure 16.11 End-to-side anastomosis for size discrepancy greater than 5:1. Window-type stoma created about 5–10 cm proximal to the anastomosis.

Vascular access in the newborn

BETH A. RYMESKI AND FREDERICK C. RYCKMAN

INTRODUCTION

Although only a small fraction of all neonates require extensive resuscitation, the large number of births throughout the world ensures that adequate neonatal intensive care facilities remain on the cutting edge of technology. Advancements in monitoring, ventilatory support, vascular access, and maintenance of core body temperature have been paramount in the vast increase in the survival rates of newborns.[1] New innovations in size and materials coupled with new routes of vascular access have been paramount for neonatologists with regard to invasive monitoring, ionotropic support, and total parental nutrition. Invasive monitoring includes both continuous blood pressure measurements and the ability to obtain arterial blood for up-to-the-minute blood gas measurements for ventilatory support. Smaller catheter size and peripheral central routes have enabled the neonatologist to maximize the use of blood products, electrolytes, drug delivery, and nutrition, especially in those neonates who are unable to tolerate enteral nutrition for long periods of time. Advances in medical devices and refinement of techniques now allow for smaller and sicker neonates to gain the same advantage that was once only available to larger infants within the intensive care unit.

ARTERIAL CANNULATION

Invasive access to the arterial system has been a mainstay in the monitoring of the critically ill patient for decades. Short-term arterial access has circumvented the need for numerous heel sticks or difficult arterial punctures for blood gas analysis utilized for ventilatory changes. Continuous blood pressure monitoring allows for up-to-the-minute decision making when using supportive vasoactive medications and can also be used to draw needed blood studies, obviating frequent venipunctures. The majority of these cannulas can be placed by percutaneous insertion techniques at the bedside.

Maintenance

Catheters within the arterial system are particularly prone to thrombosis, which guides their general care. Continuous infusion of a balanced saline solution with heparin (1 unit/mL) at a minimum of 0.5 mL/hour for all arterial lines helps to ensure patency. The type of fluid can be altered, dictated by the clinical situation. Arterial catheters are flushed with 0.5 mL of normal saline over 5 seconds after each blood draw to clear the system.

Blood pressure monitoring devices are connected by three-way stopcocks for ease of blood draws and to ensure sterility. Transducers are leveled to the phlebostatic axis (located at the fourth intercostal space and one-half the anterior–posterior [AP] diameter of the chest). The system is zeroed with the transducer in this position at the initial setup, at each shift change, and with position change of the transducer. The waveform can become dampened due to microthrombi or positioning, or from mechanical disturbances within the system. Once a waveform appears dampened, all connections are checked and secured, the tubing is evaluated for air within the system (this tends to blunt the actual pressure reading), and the catheter is then irrigated. The infant or catheter can be repositioned and the limb immobilized if necessary.

Consideration should be made of suturing the catheter in place to provide stability and promote safety. Transparent dressings (such as Tegaderm or Opsite) are utilized to facilitate inspection of the insertion site while maintaining sterility. The connections, catheter, stitches, and tubing are examined and their status documented routinely to ensure that they are intact. Intravenous (IV) fluids are changed every 24 hours, and the tubing is changed every 72 hours utilizing sterile technique. Transducers are changed every 72 hours as well. Nursing assessment of color, pulses, capillary refill, and temperature is documented every 2 hours, and the position of deeper indwelling catheters (i.e., umbilical arterial catheters) is documented with radiographs following placement and as indicated.

Complications

Most complications with peripherally inserted arterial catheters arise due to thromboembolic events or vasospasm.[2,3] Treatment is prompt removal at the first sign of blanching of the distal extremities. Further treatment includes the use of heparin or tissue plasminogen activator (tPA) and, in rare circumstances, surgical removal of clot if extremity tissue viability is compromised. Infectious complications are rare with arterial catheters as long as appropriate measures as described previously are followed.

Umbilical artery catheters (UACs) have a higher risk of thromboembolism, especially when they are placed in the low-lying position (L3–L5).[4] The infectious rates are similar to central venous catheter (CVC) rates.[3] We tend to remove these catheters within 5 days of being placed to help prevent these issues. Studies have also shown that there in no evidence that prophylactic antibiotics are useful with these catheters.[5]

UMBILICAL ARTERY CATHETERIZATION

Frequently, neonates transferred to a neonatal intensive care unit (NICU) with surgical capability have already had umbilical catheters placed at the referral hospital. Although this is not a common procedure performed by most pediatric surgeons, the ability to place these catheters is a valuable tool in the invasive monitoring of the critically ill neonate.

One or both umbilical arteries may be cannulated for continuous blood pressure monitoring or for frequent arterial blood gas measurements for ventilator management. Resuscitation fluids and medications can be delivered via these cannulas in urgent situations but are best infused using venous access sites, discussed later in this chapter. UAC placement is contraindicated in infants with omphalocele, omphalitis, umbilical cord anomalies, necrotizing enterocolitis, or signs of peritonitis or lower extremity vascular compromise.

Access technique

Catheter length should be established prior to initiating the procedure using standardized graphs, which utilize the length of the shoulder to the umbilical cord in centimeters to estimate the position of the catheter.[6] Calculations can also be performed using birth weight (BW) to estimate the desired position of the catheter (high T6–T9, low L3–L5), such as those described by Shukla and Ferrara[7]:

$$\text{Low catheter position umbilical artery (UA) length (cm)} = \text{BW(kg)} + 7$$

$$\text{High catheter position UA length (cm)} = (3 \times \text{BW(kg)}) + 9$$

Since this may not be accurate in very-low-BW infants, Wright et al.[8] suggest using the formula UA length (cm) = (4 × BW (kg)) + 7 for those infants less than 1500 g for a high-lying position. We generally attempt to place UACs in the high-lying position to theoretically decrease the rates of thrombosis and intestinal ischemia given previous studies.[4] In all cases, an abdominal radiograph is used to check the catheter position prior to the completion of the procedure (Figure 17.1).

Standard umbilical catheters measure 3.5 Fr (premature) to 5 Fr (full term) and can be purchased from various manufacturers. The infant is generally placed under a radiant warmer with the surgeon donning standard sterile equipment. The umbilical stump and surrounding abdominal skin is prepped with a surgical prep solution and the field draped. A minor instrument set including forceps, hemostats, and needle drivers is all that is needed for catheter placement. Appropriate fluids should be available to infuse into the catheter upon gaining access. We prefer to use ¼ normal saline with heparin (1 unit/mL) to keep the line patent. The catheter should be flushed with sterile saline prior to insertion. The umbilical stump is grasped, and umbilical tape is used to encircle the stump below skin level to prevent bleeding. The stump is cut with care to leave adequate length for ease of manipulation during placement. One umbilical artery is identified—the vein is normally larger and thin walled, and the arteries are small, thick walled, and normally two in number—and gently dilated with either a hemostat or forceps. Either a 3.5 Fr (infants less than 2 kg) or 5 Fr (those greater than 2 kg) previously flushed catheter is then passed into the lumen with gentle traction applied to

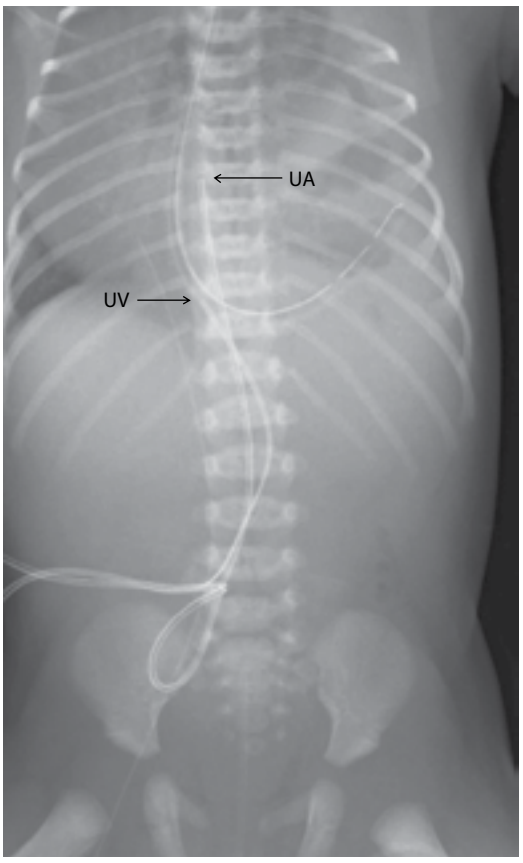

Figure 17.1 Radiograph of high-lying umbilical artery catheter (UA) and umbilical vein catheter (UV) in desired position.

the umbilical stump. Blood return is usually encountered when the catheter enters the iliac artery. The catheter is then advanced to the desired position and secured with suture through the substance of the cord. Radiographs can be used to confirm position prior to breaking sterile conditions to allow for manipulation. The desired fluids and measurement devices are then secured to the catheter by way of a three-way stopcock mechanism or manifold.

ALTERNATIVE METHOD FOR UMBILICAL ARTERY CANNULATION

At times, the umbilical cord is too short or dry to allow for easy cannulation. Access to both umbilical arteries can be achieved through an infraumbilical incision and blunt dissection through the subcutaneous tissues. Once the umbilical arteries are encountered, proximal and distal control can be gained by silk or long-term absorbable sutures. The artery can be accessed by making a transverse arteriotomy through the anterior one-half of the artery, allowing direct catheter passage. The distal control suture is tied to secure the artery and the catheter. The incision can be closed with interrupted suture and a sterile dressing applied.

RADIAL ARTERY CANNULATION

The most common site for peripheral arterial access is the radial artery. It provides a site that is ideal to access due to its consistent anatomical relationships, collateral blood flow, and easy access for nursing maintenance. Most radial arterial lines can be placed percutaneously, which helps to maintain sterility and allows for potential recannulation in the future. In rare instances, a cut-down technique is required for direct access to the artery.

Access technique

Collateral circulation of the hand should always be assessed (Allen test) and documented prior to radial or ulnar artery access attempts. Blanching or cyanosis of the fingers or hand should preclude placement. The radial artery can be palpated medial to the styloid process of the radius along the proximal wrist crease. The infant's forearm is placed on an arm board with the wrist dorsiflexed approximately 30–45 degrees (Figure 17.2). The wrist is then prepped (Betadine solution) and draped in a sterile fashion. Local anesthetic can be used but will sometimes obscure the radial pulse and is generally avoided. A 22 or 24 Fr needle catheter is inserted at approximately a 20-degree angle until blood can be seen within its hub. The catheter tip is then gently advanced into the vessel while removing the needle. If resistance is met, a small guidewire (Cook 0.015" fixed-core guidewire) can be passed into the catheter to aid in manipulation and to allow easier advancement. A T-piece connector and stopcock are then attached to the catheter, and it is flushed to ensure patency. The arterial line is then stitched into place and dressed with a transparent dressing. Ultrasound guidance

Figure 17.2 Positioning for radial arterial catheter.

to identify the radial artery and visualize the needle in the center of the artery can be helpful when utilized by providers who are trained to use ultrasound for vascular access.

If a cut-down approach is necessary, a small transverse incision can be made proximal to the joint over the point of maximal impulse. Blunt dissection is usually all that is necessary parallel to the vessel course for adequate exposure. Once exposure is obtained, proximal and distal control is secured with silk or long-term absorbable suture ties. Once again, a 22 or 24 Fr catheter is used to gain percutaneous access with gentle traction on the distal control suture. A guidewire (Cook 0.015" fixed-core guidewire) can also be useful in this setting to guide the catheter into place once blood is obtained within the hub. Backflow of arterial blood ensures successful placement. Distal vascular occlusion to prevent backbleeding is generally not necessary, and the control sutures can be removed following the procedure. The skin site is then closed with interrupted sutures, and the catheter is sutured into place at the skin level. The catheter is then dressed and accessed in a similar manner as earlier described.

PEDAL ARTERIAL CANNULATION

The next most commonly used sites for arterial cannulation are the posterior tibial and dorsalis pedis arteries. Once again, these sites allow for collateral blood flow and easy maintenance. Access can be obtained percutaneously or by cut-down. The anatomical relationship of the posterior tibial artery posterior to the medial malleolus provides an easy site for surgical access. Insertion techniques are similar to those described for the radial artery. The line is then immobilized in a similar manner.

AXILLARY AND FEMORAL ARTERIAL CANNULATION

These sites are generally reserved for emergent situations where peripheral arterial pulses are weak and access is unobtainable. The high risk of vasospasm and embolization to the extremities and minimal collateral blood flow

preclude their everyday use. In the urgent situation that these lines are required, they should be removed as soon as clinically possible.

Percutaneous access can be obtained via the axillary artery with the arm extended beyond the horizontal and midway through its course. A guidewire is generally not needed for this catheter placement. Access to the femoral artery can be gained below the inguinal ligament also by percutaneous methods. Guidewires are generally used to ensure correct position within the iliac artery. They are secured in a similar manner to the peripherally placed lines.

VENOUS CANNULATION

The ability to gain venous access in newborns has been available for decades and allows neonatologists and surgeons the ability to provide consistent vascular access to deliver critical care. New catheter materials including plastic and silicone allow for small-bore devices and the cannulation of the smallest of veins. Temporary peripheral access can be easily obtained in the newborn at the bedside with 24 Fr angiocatheters or by umbilical vein catheterization. This access, however, is temporary, and often, central IV access is needed for long-term parental nutrition or vasoactive medication drips.

Newer access methods including peripheral intervenous central catheters (PICCs) are now the mainstay for central venous access in the neonatal intensive care setting. The ability to insert these catheters at the bedside, coupled with decreased expense and rapid insertion times, has significantly decreased the need for both cut-down and umbilical catheter access in these babies. Occasions still arise when a PICC line is unable to be placed, is of insufficient size to accommodate all of the needs of the patient, or emergency resuscitation dictates the need for expedited central venous access. It is imperative for the pediatric surgeon to be skilled in all these access modalities.

Maintenance

Many hospitals have established designated central line teams to manage the everyday care of CVCs. Dedicated care teams in combination with nursing staff familiar with the care protocols and requirements are central to providing consistent daily care for CVCs.

Umbilical vein catheters (UVCs) are cared for in a similar manner as described earlier for UACs. Fluids are maintained at a minimum of 1.0 mL/hour to ensure line patency. Lines are flushed in a similar manner, and the length and position of the catheter are documented with radiographs after the initial placement (ideal placement is at the junction of the inferior vena cava [IVC] and the right atrium), as is their length every shift by the bedside nurse. Connections are checked hourly, and padded hemostats are available at the bedside for accidental disconnections. All fluids and tubing are changed in a similar manner to UACs. Discontinuation of either the UAC or UVC is performed by the physician, nurse practitioner, or qualified bedside nurses. Only 3–5 minutes of firm pressure is needed to maintain hemostasis.

Percutaneous and tunneled catheters are maintained in a similar manner. Access to the CVC via the hub, cap, or manifold is preceded by a 30-second scrub and 30-second air-dry time with 2% chlorhexidine gluconate with isopropyl alcohol (ChloraPrep). Heparin volumes for unused ports vary depending on the size of the line. We utilize the Biopatch protective disk (Ethicon) to cover and surround all insertion sites for CVCs. This disk and dressing is changed at a maximum of every 7 days or if the site appears erythematous or the dressing is compromised. The Biopatch should be used with caution in neonates under 1000 g as there has been reported a 15% incidence of contact dermatitis versus a 1.5% incidence in neonates ≥1000 g.[9] The site is cleansed with a 30-second ChloraPrep or 60-second povidone scrub. A new Biopatch and transparent occlusive dressing (Tegaderm or Opsite) is then applied after the site has completely dried. All CVCs are checked hourly and documented by the bedside nurse. Each shift, the nurse documents the position of any sutures, skin integrity, redness or induration, the position of the cuff in tunneled lines, occlusiveness of the dressing, changes in the extremity, and any site of pain or discomfort. Cut-down sites are maintained in a similar manner. Although uncommon, intraosseous (IO) needle sets can be placed in an emergency situation but are removed within 24 hours of placement. Povidone iodine–soaked gauze is placed around the insertion site and is changed every 2–3 hours or when the gauze is dry. Particular attention is paid to the hemodynamic status of the limb for any signs of compartment syndrome.

Complications

Complications associated with central lines are numerous, but most can be avoided with careful placement techniques and nursing care. Pneuomothorax, chylothorax, lung injury, malposition of the line, and perforation of the vessel are but a few of the many issues that can arise during the initial placement.[10] Cardiac arrhythmias can occur due to stimulation of the endocardium in those patients whose line is placed deeper than the superior vena cava/right atrial junction. This can be avoided in most cases by using fluoroscopy when placing subclavian or jugular venous access lines. Tunneled line expulsion is very uncommon when using Dacron cuffed tunneled lines.

Neonates in particular are susceptible to thrombosis near the catheter tip of CVCs given their small vessel. Even with continuous heparin infusion, up to 30% of neonates with CVCs have some form of thrombosis detected.[11,12] Most episodes of thrombosis are asymptomatic and generally present as inability to flush or withdraw blood from the CVC. tPA can be utilized to remove clot buildup on the catheter tip. This is usually successful and can be repeated for stable clots. Continued buildup of clot demonstrated by ultrasonography may necessitate removal of the line. Several papers have documented an increased rate of thrombosis in infants with abdominal pathology, particularly gastroschisis, who have lower extremity PICC placement.[13,14] In these patients,

consideration should be made of placing only upper extremity or jugular access. One should be weary of removing lines in neonates unless the child is symptomatic due to the relative difficulty in placing and maintaining these lines. Rarely do neonates require heparin therapy following removal.[15]

The most common complication of any central catheter is infection. Historically, rates of central line–associated blood stream infection (CLABSI) as high as 29% have been seen in neonates, with smaller infants at greatest risk.[12,16] Differences in infection rates can be attributed to differences in patient populations and practice guidelines.[12] CLABSI has received a lot of attention in the past 10 years, which has resulted in a significant decrease in the infection rate. Particularly, creation of care "bundles" to standardize care and enforce best practice policies has been shown to decrease CLABSI rates even in high-risk infants.[17] Coagulase-negative staphylococci continue to be the most common cause of central line infection and bacteremia. Numerous other bacteria including gram-negatives, anaerobes, and *Candida* species can cause line infection, especially in the postsurgical neonate. Although many authors advocate treatment with antibiotics for the clearance of central line infection, removal of the foreign body (CVC) associated with the infection may be needed in refractory cases. PICC lines can be inserted as a bridge to replacement of more permanent access during antibiotic treatment of the bacteremia. Insertion site infections can generally be treated with antibiotics alone and do not require removal of the catheter unless bacteremia is documented. With careful guidelines for the placement and maintenance of these catheters, very low infection rates can be achieved.

PERIPHERALLY INSERTED CENTRAL CATHETER

The majority of centrally placed lines in most neonatal units are PICC lines. These lines can be quickly placed by specially trained nursing personnel, radiologists, or pediatric surgeons at the bedside with little to no sedation. The catheters are made of silicone or polyurethane and come in sizes as small as 1.9 Fr. In contrast, the smallest surgically placed lines are usually 2.7 Fr catheters. This small size allows for placement in neonates as small as 500 g. Although the initial experience with PICC line placement used fluoroscopy for all cases.[18] This is now generally reserved for those infants who have failed multiple attempts at bedside placement.

Access technique

Sterile technique is maintained throughout the procedure. After the appropriate site is chosen (antecubital, saphenous, or scalp veins), the catheter is flushed with heparinized saline 2 units/mL. The proposed length of the catheter is then measured. The site is cleansed with a surgical prep and draped in a sterile fashion, and a tourniquet is applied. Ultrasound is utilized to identify the target vein, and the introducer needle set is then inserted into the vein with return of blood flow confirming position. The catheter is then advanced through the peel-away introducer in 1 cm increments to the premeasured length. The catheter can be flushed with normal saline to facilitate insertion. Once the desired length is reached, blood is aspirated, and the line is flushed with heparinized saline. The breakaway needle is released, and a securement device is placed. Steri-Strips are applied and a Biopatch placed over the insertion site with a transparent dressing as a covering. A chest radiograph confirms the position of the catheter tip.

UMBILICAL VEIN CATHETER

The majority of UVCs are placed by neonatologists at outside facilities prior to transfer. These lines can be used for emergency medications, fluids during resuscitation, transfusions, and longer-term central access for IV fluids. The complications are similar to other CVCs but do have an increased risk of infectious complications of the liver and heart.[3] The generally accepted optimal position for UVC placement is the tip at the level of the IVC/right atrial junction. Cardiac arrhythmia can occur with placement of the UVC within the heart itself and is the most common complication during insertion. Cardiac perforation with pericardial tamponade and subsequent demise has been reported with deep insertion.[19] Portal hypertension can occur with placement into the portal system secondary to extrahepatic portal vein thrombosis. Portal vein thrombosis is a known complication, I would not include hepatic necrosis. We have seen cardiac perforation with line advancement when ascites decreased (urinary ascites from perforated renal pelvis).

Access technique

The placement of the UVC catheter is similar to the previously described placement of the UAC. A 3.5 or 5 Fr catheter is used to gain access to the single umbilical vein. Catheters are advanced gently, usually only 1–2 cm beyond the point of blood return (generally only about 5 cm in a term infant). Radiographs confirm the position of the catheter preferably at the level of the diaphragm (Figure 17.1). The catheter is maintained similarly to the UAC.

Access can also be gained in emergency situations in the operating theater in the newborn by a supraumbilical incision with gentle dissection and cannulation of the vein along the abdominal wall. This site is usually only viable for a few days prior to closure.

PERCUTANEOUS CANNULATION

Multiple sites can be utilized for the percutaneous introduction of CVCs, including the internal jugular veins, subclavian veins, and femoral veins. Although these can be placed at the bedside in extreme conditions, they are more safely placed in the operating room under general anesthesia with ultrasound or fluoroscopic guidance. The technique of ultrasound-guided placement of central venous lines is

particularly effective for the internal jugular vein[20] and is a helpful technique at any age. The improved safety with this placement technique is quickly establishing this as best standard practice. We utilize fluoroscopy liberally while placing any centrally dwelling catheter in the operating room. This not only helps to confirm placement but also allows direct vision while dilating vessels and advancing catheters into the correct position with the Seldinger technique.

Access technique

Percutaneous access for central line placement is accomplished by the use of the guidewire (Seldinger) technique. The patient is placed supine on the operating table, and a small towel roll or bump is placed under his/her shoulders to extend the neck with the head midline. Both sides of the neck and chest are prepped and draped in the standard fashion. The patient is then placed in the Trendelenburg position. The two standard infant-sized Broviac tunneled catheters are the 2.7 Fr and 4.2 Fr single-lumen catheters (Bard, Salt Lake City, Utah, USA). Temporary nontunneled 4 Fr double-lumen catheters are also available (Cook, Arrow). We prefer for the child to be at least 10 lb. before placing a double-lumen catheter given its size. Standard introducer sets contain introducer needles, guidewires, and introducer sheaths with dilators. In the central approach for internal jugular venous access, the vein lies at the apex of the sternal and clavicular heads of the sternocleidomastoid (SCM) muscle. Ultrasound guidance is particularly useful in identifying the vein. Once the vein has been accessed and the guidewire placed, fluoroscopy is utilized to confirm position. A site on the chest is chosen, and the catheter is tunneled from this site to the insertion site. We prefer to use live fluoroscopy to pass the dilator sheath complex over the guidewire and to measure the appropriate length of the catheter. The dilator and guidewire are then removed, and the catheter is placed via the peel-away sheath and into position. The final position of the line is confirmed with fluoroscopy. Incisions are closed, and a Biopatch and transparent, occlusive dressing are applied. This same technique can be used for percutaneous femoral vein catheterization. Subclavian vein access can be facilitated by ultrasound guidance, but the technical considerations are more difficult given the location of the clavicle. Generally, the landmarks of the mid angle of the clavicle and the sternal notch are used for subclavian venipuncture with fluoroscopy used in a similar manner as described.

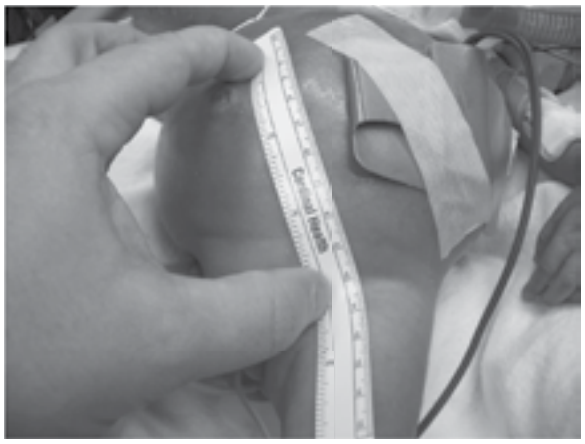
The femoral vein can also be accessed at the bedside by first using a 24 Fr angiocatheter to gain access. A small guidewire (Cook 0.015" fixed-core guidewire) passes easily through this sheath. A larger angiocatheter can then be placed over the wire to facilitate the larger guidewire in the temporary central line set. Abdominal radiographs can then confirm position.

PERIPHERAL VEIN CUT-DOWN

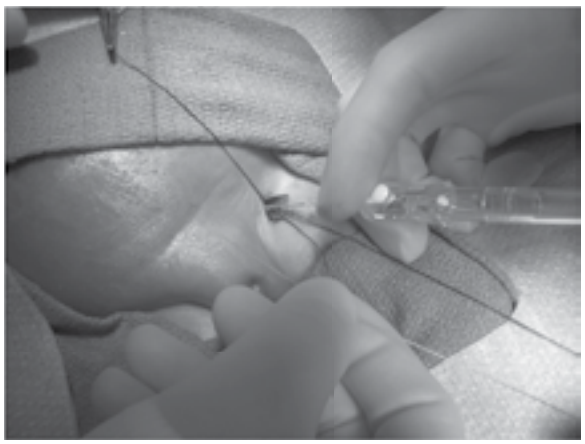
With the significant increase in PICC lines placed at our institution, we have seen a dramatic decrease in the number of peripheral vein cut-downs performed. These now seem to be reserved for those small infants where percutaneous methods are impossible. The common facial vein, external jugular vein, internal jugular vein, and saphenous vein are the most commonly used sites. With excellent nursing care and sterile technique, the infection rates are comparable to the percutaneous route of cannulation.

Access technique

The saphenous vein can be accessed at numerous points along its course. The most distal site is just superior to the medial malleolus. This site is not useful for long-term access and is not central in its location. The saphenous vein drains into the femoral vein at the level of the femoral triangle and is an easy access point for central cannulation. The infant is placed in a supine position, and a rolled towel is placed under the pelvis to allow easier access. The groin is prepped and draped in the standard fashion. The length of the catheter can be measured by the length from the proposed incision to just superior to the umbilicus (iliac vein/IVC junction) (Figure 17.3) Ultrasound can be used



(a)



(b)

Figure 17.3 **(a)** Measurement for length of saphenous vein cut-down central line. **(b)** Access of the saphenous vein with 24 Fr angiocatheter.

to identify the vessels and aid in planning the location of the incision. A transverse incision is made inferior to the groin crease inferior to the inguinal ligament. Gentle dissection in carried out parallel to the expected path of the vessel with a hemostat until the saphenous vein is found. The vein is then elevated, and proximal and distal control is gained with 5-0 silk ties. At least 1 cm of the vein should be exposed to allow for easy cannulation. The distal control ligature is then elevated to put tension on the vessel. A 24 Fr angiocatheter is then used to gain access to the vessel and is advanced as the needle is removed (Figure 17.3). Care must be undertaken to avoid going through the back wall of the vein. A small guidewire (Cook 0.015" fixed-core guidewire) can then be advanced into the angiocatheter, allowing a 22 Fr angiocatheter to be placed, which is large enough to accommodate the guidewire found in most 3 or 4 Fr central line kits. The catheter is then advanced, and the proximal suture is tied down to secure the line and the vessel. The distal ligature can be removed or tied down if there is significant back-bleeding. The incision is then closed in the usual fashion, and the line site is dressed as previously described.

CENTRAL VEIN CUT-DOWN

Neck cut-down for access to the common facial vein or the internal jugular vein is also useful in neonates. This procedure can be performed bedside in the NICU with x-ray available to confirm line position. Typically, the right neck is used to take advantage of the drainage of the jugular vein directly into the superior vena cava. With a roll under the infant's shoulders and the head turned to the left, a transverse incision is made along the anterior border of the SCM one-third of the distance below the angle of the mandible and the clavicle. The SCM is exposed and retracted laterally to expose the vessels. The internal jugular vein is identified and the common facial vein branch dissected free. If the common facial vein is not useable (too small, aberrant anatomy, etc.), then the internal jugular can be used. Proximal and distal control is obtained around the target vein with silk or long-term absorbable suture. The distal side is tied off and a small venotomy made on the anterior vein wall. A vein pick may be helpful to better expose the vessel lumen. The catheter, which should be measured against the patient's body and is tunneled per the usual technique, is then introduced through the venotomy and advanced. Cutting the tip of the catheter in a beveled manner may assist with this process. The proximal tie can be secured lightly around the vessel and catheter with care to not occlude the small lumen. An x-ray should be obtained to confirm the position of the tip, and the catheter should draw blood and flush easily. Cannulation of the external jugular vein has also been utilized, but the angle of the vessel joining the subclavian may make passage of the small catheter difficult. The incision is then closed and the catheter dressed in the usual sterile fashion as described previously in the chapter.

INTRAOSSEOUS DEVICES

During trauma or emergency resuscitation, the venous system may be collapsed due to hypovolemia and shock. Gaining intervenous access in these cases can be quite challenging and time consuming. A quick and easy alternative is the placement of an intraosseous device. These devices come in a multitude of sizes, with the smallest available in our facility being 1.8 mm × 15 mm in length. Contraindications to their placement include fracture, absence of landmarks, infection at the proposed insertion site, and previous instrumentation of the extremity. These devices have gone through many evolutions and have a very low (<1%) complication rate.[1] The EZ-IO system (Vidacare, San Antonio, Texas, USA) allows for quick and stable access even in the newborn.

Access technique

For infants between 3 and 39 kg, the small, 15G needle system can be effectively used (Figure 17.4). The two most common insertion sites are the proximal tibia just below the tibial tuberosity and, less commonly in infants, the humerus at the level of the humeral head. Local anesthesia can be injected at the proposed insertion site once it is prepped and draped. The needle is inserted into the driver system, and the needle cap is removed. The needle and driver should be positioned at a 90-degree angle to the bone. The needle is then pressed into the skin until the tip touches the bone (ensure that at least 5 mm of the catheter is still visible at this point). The bone cortex is penetrated by squeezing the driver's trigger and applying gentle, steady downward pressure. Once a sudden give or pop is encountered, the medullary space has been entered. The driver and stylet are removed, and the catheter is flushed with at least 5 mL of normal saline. If the catheter flushes well, fluids and medications can be administered.[21] A dressing is placed around the device and changed on as needed. IO devices should be removed within 24 hours to avoid complications such as osteomyelitis and compartment syndrome.

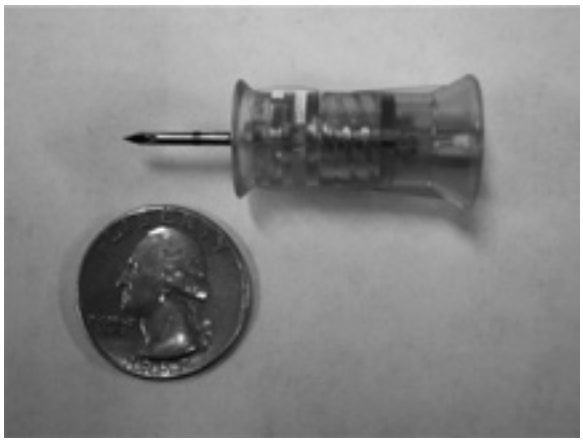


Figure 17.4 15G intraosseous needle (Vidacare, San Antonio, Texas, USA).

CONCLUSION

With smaller, critically ill neonates being managed in our intensive care units, reliable vascular access is a necessity. Improvements in techniques, miniaturization of catheters, and development of new materials allow for stable access and improved care in premature and newborn infants. As these catheters continue to evolve, newer and safer techniques will soon follow.

Radiology in the newborn

J. KELLEHER, IAN H. W. ROBINSON, AND ROISIN HAYES

INTRODUCTION

During the past decade, significant developments in surgical techniques, anesthesia, and intensive care have advanced and improved care of the sick newborn baby. All imaging modalities have reached a new higher level of sophistication, and the range of invasive and interventional radiology procedures has also greatly increased. These advances have placed greater demands on pediatric radiology departments, which must be well staffed, funded, and equipped to keep pace with these developments. Because of the plethora of available investigations, it is essential that both conventional radiographic and high-technology imaging facilities be used efficiently and rationally. A logical sequence of investigations should be applied, commencing with the simplest and least invasive, and where possible, minimizing exposure to ionizing radiation. At all times, the ALARA principle (as low as reasonably achievable) should be foremost in our mind. This approach may provide the diagnosis and obviate the need for more complex, invasive, and expensive studies, even if these additional modalities are readily available. Duplication of information obtained from these various imaging modalities, which does not improve or influence management of the patient, should be avoided.

CONVENTIONAL RADIOGRAPHY

Plain radiography is often the first and most useful study in the evaluation of the surgical neonate. Radiographic examinations should be directed to achieving the required information with the minimum of handling or disturbance while maintaining the infant's body temperature and employing measures to limit radiation exposure. Only relevant projections should be obtained in relation to the clinical problem and condition of the baby (Figure 18.1). There is no longer a place for routine lateral chest views.

Examination rooms should be kept warm—around 80°F (27°C)—and the baby should be removed from the warm protective environment of the incubator for the shortest possible time. The use of the newer generation of "giraffe"-type incubators has greatly facilitated the examination of fragile neonates.

High-frequency generators, added beam filtration, and digital image receptors all contribute significantly to reducing the radiation burden to the infant.[1] The beam should be collimated to cover only the relevant area, and gonad protection with lead shields should be used. Where repeated examination of the chest and mediastinum is anticipated, the use of thyroid shielding should be considered. Good radiographic technique is essential to produce radiographs of high quality, thus avoiding the unnecessary extra irradiation and disturbance of babies resulting from repeat exposure.[2] A sufficient number of well-trained and experienced radiographic technicians should be available to ensure that these high standards are maintained.

MOBILE EXAMINATIONS

In recent years, a great increase in demand for portable radiographic examinations has occurred. The position of vascular access catheters and endotracheal tubes may need to be repeatedly checked, and frequent examinations may be required in infants with severe respiratory problems on ventilation.[3] Mobile x-ray machines have become smaller and more maneuverable and give shorter exposure times. Incubators chosen for special or intensive care baby units should be user-friendly for radiography.

Lateral decubitus views of the chest or abdomen using a horizontal beam are easily performed on babies while in their incubators. They can be very useful in demonstrating pneumoperitoneum and in evaluating fluid levels in bowel (Figure 18.2). A dorsal decubitus view of the abdomen is perfectly adequate to either confirm or exclude pneumoperitoneum and is obtained without any re-positioning of the infant in the incubator (Figure 18.3a–c). Erect views should no longer be requested or performed.

Protocols should be in place to maximize the information obtained while minimizing the disturbance and distress to the infant. Our previous practice of performing

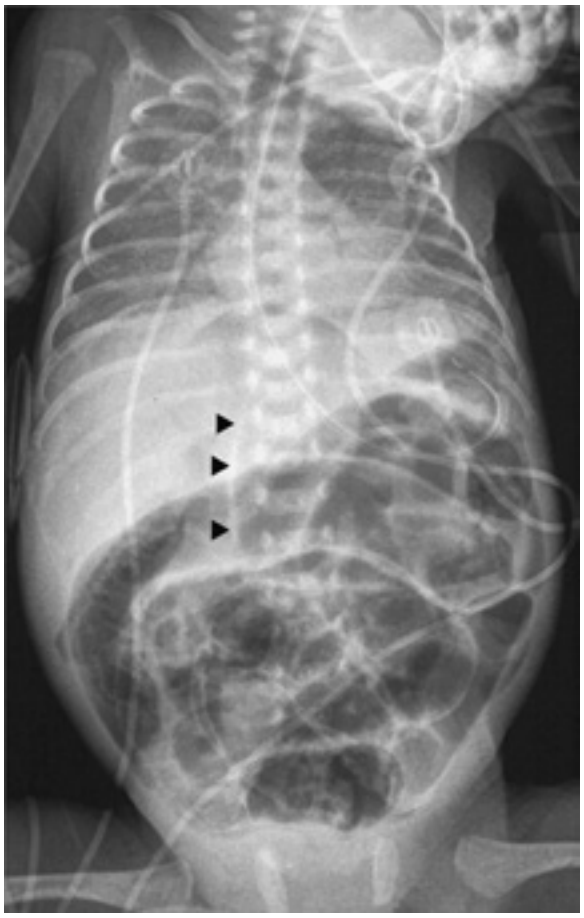

Figure 18.1 Supine chest and abdomen. Supine x-ray of the chest and abdomen in a premature neonate demonstrates abnormal increased lucency over the liver, with free intraperitoneal gas clearly outlining the falciform ligament (arrowheads). A decubitus x-ray is not required in this situation as the diagnosis of perforation is already made. Also evident is intramural gas in keeping with necrotizing enterocolitis and diffuse granular pulmonary parenchymal opacity with central air bronchograms, typical of surfactant deficiency syndrome.

inverted lateral radiographs for anorectal anomalies involved the baby being removed from the incubator and held upside down by its legs while the exposure was taken. Aside from the trauma to the infant, it is difficult to obtain a good true lateral view centered at the correct level. A prone lateral view with the buttocks elevated and using a horizontal x-ray beam is a far superior technique. The baby can be left comfortably in this position for a period of time to ensure that gas outlines the distal limit of the blind rectal pouch (Figure 18.4a,b).

FLUOROSCOPIC EXAMINATIONS

For investigations in neonates, the fluoroscopy room should be warm, with oxygen and suction outlets readily available. A fully equipped resuscitation trolley should be at hand. Procedures should be carried out quickly but carefully. Good

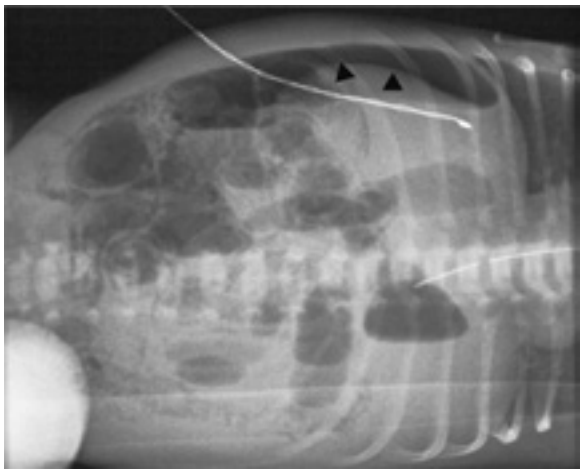

Figure 18.2 Left lateral decubitus. Decubitus x-ray in a neonate with perforated necrotizing enterocolitis. The free intraperitoneal gas rises, outlining the liver (arrowheads). Intramural gas in keeping with necrotising enterocolitis is also demonstrated. The decubitus x-ray is also useful in the detection of air–fluid levels.

venous access should be ensured before commencing any invasive or interventional procedure. The radiologist should concentrate on solving the clinical problem presented and tailor the study accordingly.

Developments in computerized digital fluoroscopy in recent years have resulted in the potential for a marked reduction in radiation exposure, more rapid performance of dynamic contrast studies, and greatly improved recorded images. Digital fluoroscopy units often have the facilities to provide a rapid series of exposures at up to 30 frames per second. While this can be very useful in studies of the swallowing mechanism or of the airway, the ability to store and review a *video loop* is much more valuable. The use of appropriate reduced-rate pulsed fluoroscopy greatly reduces radiation dose. A *last-image hold* facility allows relevant images to be saved, with no additional radiation. In most neonates, it should be possible to screen without a *grid*, thus further reducing radiation dose, and the use of magnification should be minimized. Modern installations provide image enhancement, processing, and digital subtraction facilities, which are very useful in angiography.[4]

Nonionic water-soluble contrast media are used for all intravascular studies in children. Such contrast agents can also be used for gastrointestinal examinations. They permit excellent anatomic delineation and may be safely used even where leakage into the mediastinum or peritoneal cavity, or gastrointestinal obstruction, is suspected. They are well tolerated even if pulmonary aspiration occurs, though some element of pulmonary edema may develop. If diluted, an iso-osmolar solution can be achieved for even greater tolerance in the airway. If a tracheoesophageal fistula is suspected, a feeding tube can be inserted into the proximal esophagus, through which nonionic contrast is injected under fluoroscopy, as demonstrated in Figure 18.5.

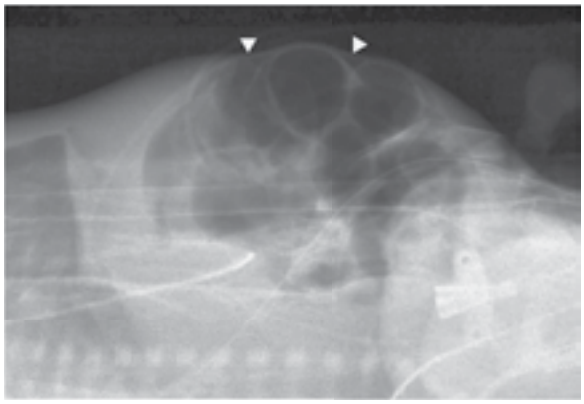
(b)



(c)

Figure 18.3 **(a)** Dorsal decubitus. Position of baby in incubator for horizontal beam exposure. **(b)** Dorsal decubitus—large amount of free gas. In the dorsal decubitus position, a large amount of free intraperitoneal gas clearly outlines the diaphragm, liver, and bowel loops. **(c)** Dorsal decubitus—small amount of free gas. Even small amounts of gas may be detected in the dorsal decubitus position, outlining the anterior abdominal wall and adjacent bowel, as in this case (arrowheads), or anterior to the liver.

Conventional ionic contrast agents, e.g., Urografin (Bayer) 30%, are less expensive and are appropriate for micturating cystourethrography (Figure 18.6). All infants should have appropriate antimicrobial cover during micturating cystourography (MCUG) to reduce the risk of infection. The contrast agent should be warmed to body temperature and may

be diluted with sterile water. Either a 5F or a 6F feeding tube is used to catheterize the baby. In males, a steep oblique view of the urethra must be obtained during voiding to exclude the presence of posterior urethral valves. Screening time can be kept to a minimum by observing the flow of contrast from the bottle. When flow stops, the baby is usually ready to urinate.

ULTRASONOGRAPHY

This relatively inexpensive and widely available imaging modality has transformed neonatal diagnostic imaging. Lack of ionizing radiation, portability, and the freedom to do serial repeat studies make it especially suitable for this patient population. In premature or severely ill babies, ultrasonographic (US) scans can be performed satisfactorily without removing the infants from their incubators. The principles of minimal handling and maintenance of body temperature apply. Examinations should be carried out quickly and efficiently, aimed at achieving a diagnosis and not prolonged or repeated just to produce the "perfect picture."

Congenital structural abnormalities are being diagnosed with increasing frequency on antenatal scans. Many congenital brain malformations and spinal anomalies are easily recognized.[5] Prenatal recognition of anomalies such as cystic adenomatoid malformation, cystic renal disease, or

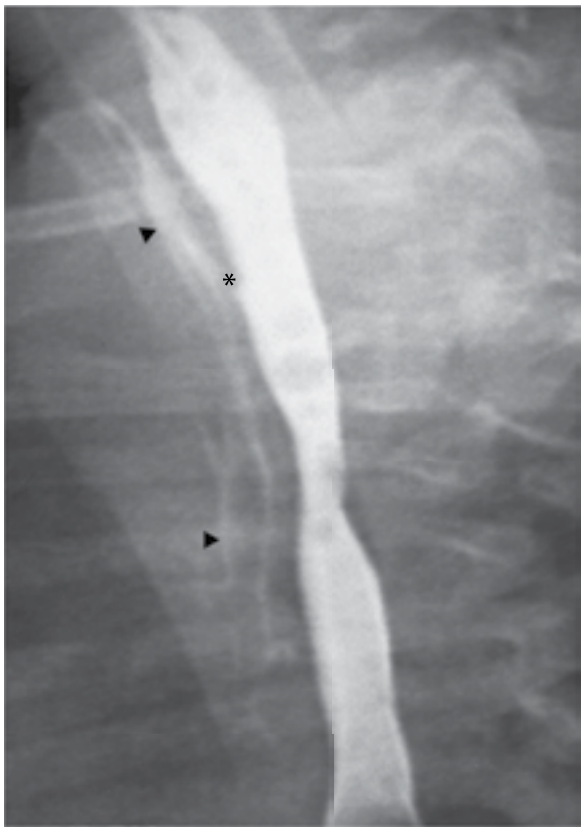

Figure 18.5 H-type tracheo-esophageal fistula. Water-soluble contrast fills the esophagus and passes through an H-type fistula (asterisk) into the trachea (arrowheads).

Figure 18.6 Micturating cystourethrography. Lateral image of the bladder and urethra in a male infant taken during micturition. The bladder is abnormal in contour, and the posterior urethra is markedly dilated (asterisk). The thin filling defect representing the membrane of the posterior urethra valve is visible (arrowheads).

intestinal tract obstructions alerts the neonatologist to the need for careful postnatal evaluation.

The identification of abdominal wall defects such as exomphalos and gastroschisis or of a diaphragmatic hernia on an antenatal scan allows the delivery to be arranged in or close to a major pediatric surgical center. Ex utero intrapartum treatment (EXIT surgery) can be planned if major airway problems are detected in utero. Antenatal interventional techniques can be performed under US guidance, e.g., the insertion of stents or drains in obstructed urinary tracts.

Cranial US is now an indispensible facility in any department dealing with newborn patients.[6] Using high-frequency transducers, images of excellent detail are obtained. Hydrocephalus secondary to intraventricular hemorrhage (IVH) or myelomeningocele can be accurately diagnosed and graded. Serial examinations are helpful in relation to the need for shunting. However, if the cause of the hydrocephalus is not evident, then further investigation using magnetic resonance imaging (MRI) may be necessary. One of the most important contributions of US is in the diagnosis and grading of IVH. Early diagnosis of minimal lesions can be achieved in infants at risk. The discovery of IVH can influence the decision to operate on a newborn with a congenital malformation if IVH is severe (Figure 18.7).

There is an increasing use of ultrasound in evaluating suspected anomalies of the spinal cord in infants. Ultrasound can demonstrate a broad spectrum of intraspinal anatomy, both normal and abnormal, and define pathological conditions with a high degree of accuracy in infants under 4 months of age.[7] It may obviate the need for MRI (Figure 18.8).

Sonography plays a significant role in the investigation of mass lesions in the neck and mediastinum. It permits localization, assessment of relationships to surrounding structures, and especially differentiation of cystic from solid

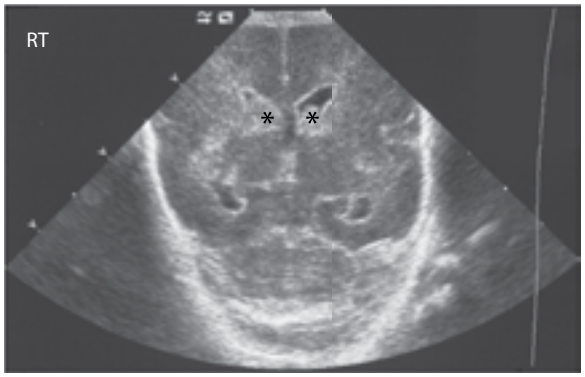

Figure 18.7 Cranial US. Coronal US image of the brain in a premature neonate. Hemorrhage is visible within both lateral ventricles (asterisk). The ventricle wall is echogenic. In addition, there is increased echogenicity within the periventricular parenchyma on the right, in keeping with infarction, indicating a Grade 4 intraventricular hemorrhage on this side. Note the relatively poor sulcation typical of a premature infant.

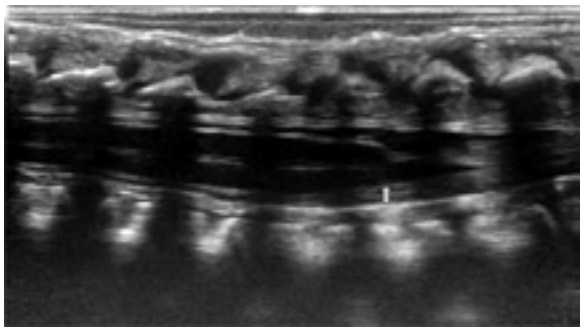

Figure 18.8 Ultrasound spine. This clearly depicts abnormal wedge-shaped truncation of the spinal cord (arrow) typical for caudal regression, in a newborn baby with anorectal malformation and lumbosacral dysgenesis.

lesions (Figure 18.9a,b). Real-time sonography is very useful in evaluating phrenic nerve paralysis.

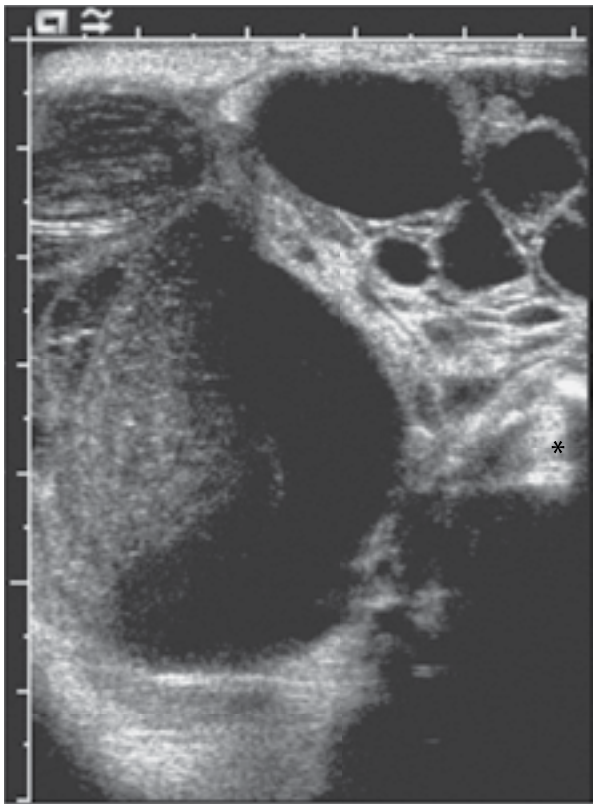
Abdominal US is very frequently carried out in the newborn to diagnose or exclude renal disease. Lesions confined to the kidneys include multicystic dysplastic kidney, polycystic disease, and hydronephrosis. The latter may be due to obstruction at the pelviureteric or ureterovesical level or to severe reflux. In males, it may relate to the presence of posterior urethral valves. All of these conditions are readily diagnosed with US, and the severity of obstruction and renal damage can also be assessed. The kidneys are frequently involved in complex syndromes, e.g., VACTERL syndrome. The spectrum of renal anomalies varies from agenesis to crossed fused ectopic and duplex kidneys.

Ultrasound is well established as the optimal diagnostic tool in the routine evaluation of infantile pyloric stenosis. While pyloric stenosis is rare in the first 2 weeks of life, it has been reported, and the standard ultrasound measurement criteria may not be valid in this patient population.[8]

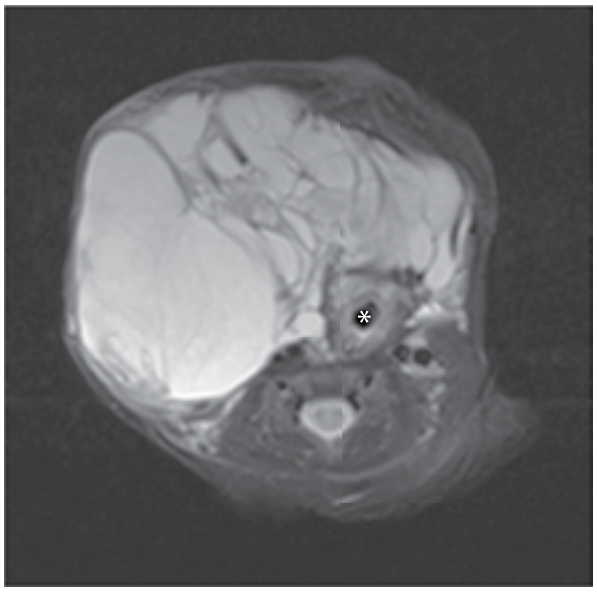
In the evaluation of mass lesions in the neonatal abdomen, US should be the first investigation. It can identify the organ of origin and help to characterize the lesion, differentiating cystic from solid. Figure 18.10 shows the typical cystic appearance of neonatal adrenal hemorrhage. In comparison, Figure 18.11 demonstrates a solid suprarenal mass, confirmed to be neuroblastoma, stage 4S. If a definitive diagnosis cannot be made on US, it should at least give a clear indication as to the next logical investigation.

In neonatal jaundice, US plays a key role in defining the anatomy of the biliary tract. Choledochal cyst may be diagnosed with confidence and biliary atresia excluded. It can demonstrate or exclude dilatation of the biliary duct system (Figure 18.12). Radionuclide imaging may have a complimentary role to play.

The development of Doppler, including color Doppler, has been a considerable advance with widespread application. The safe placement of vascular access lines is greatly aided by this technique. It can accurately map the vascular anatomy of abdominal masses or of arteriovenous



(a)



(b)

Figure 18.9 **(a)** Ultrasound of neck—cystic hygroma—plus accompanying **(b)** magnetic resonance imaging (MRI). US and MRI are complementary modalities. US has superior spatial resolution, for example, being able to detect thin septations. MRI, however, allows a more accurate assessment of the overall extent of a lesion and its relation to adjacent structures. In this example, the trachea is visible on both the US and MRI (asterisk).

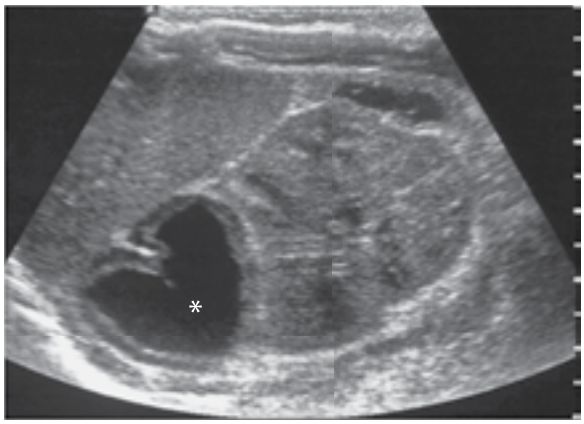


Figure 18.10 Ultrasound of adrenal hemorrhage. Cystic enlargement of the adrenal gland typical of an adrenal hemorrhage (asterisk).

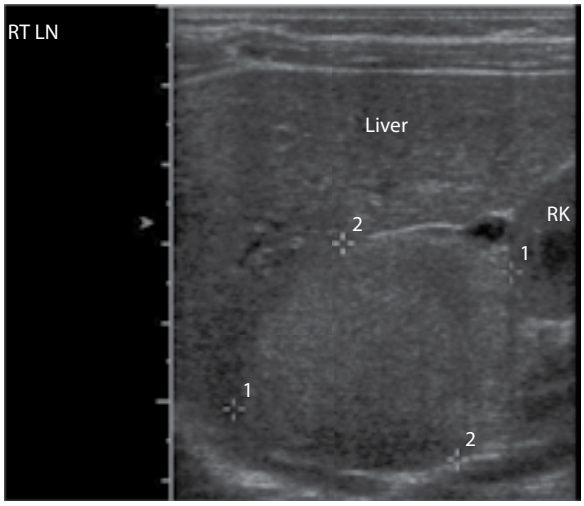

Figure 18.11 Ultrasound adrenal neuroblastoma. In contrast, this suprarenal mass is clearly solid and is typical for a neuroblastoma. (RK = right kidney.)

malformations in other sites. It allows noninvasive imaging of hepatic vascular structures.

NUCLEAR MEDICINE

With the great advances in ultrasound, computed tomography (CT), and MRI, the role of radionuclide examinations is very limited in the newborn period. Functional rather than morphological studies are usually required. Total and individual renal function can be assessed, but due to functional immaturity, imaging is less reliable than in the older infant or child. Technetium-99m-labeled mercaptoacetyltriglycine (MAG 3) is used for assessment of obstruction, with technetium-labeled dimercaptosuccinic acid (DMSA) employed for static imaging and to demonstrate the functioning renal parenchyma. Either method will give an estimate of relative renal function. Excretory/intravenous urography or IVU has no place in modern neonatal imaging.

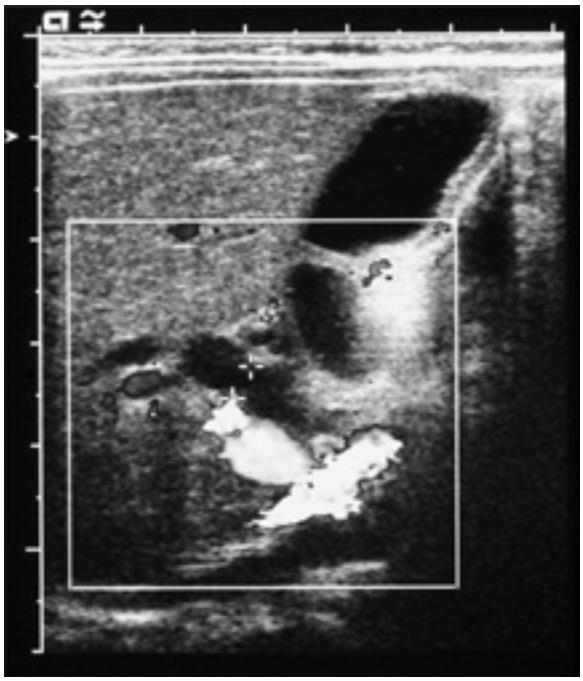

Figure 18.12 Ultrasound bile duct dilatation. US reveals dilatation of the common bile duct (calipers) in this neonate with gallstones. Color Doppler imaging is often used as in this instance to identify vascular structures separate from the bile duct.

Hepatobiliary scintigraphy is extremely useful in the investigation of neonatal jaundice where biliary atresia is a concern. The infant is given phenobarbital, 5 mg/kg per day divided into 2 equal doses, for 3 to 5 days prior to the scan, in order to induce liver enzyme activity. Mebrofenin labeled with technetium-99m (Choletec) is preferred in infants because of its greater hepatic extraction. The scan will usually differentiate between biliary atresia and neonatal hepatitis (Figure 18.13). If the biliary tract is patent, isotope should be detected in the intestine within 60 minutes.

Though uncommon, Meckel diverticulum may present with rectal bleeding in the newborn period. It can be elegantly demonstrated on technetium pertechnetate scintigraphy (Figure 18.14).

Isotope bone scanning is very unreliable in the diagnosis of osteomyelitis and/or septic arthritis in neonates and is rarely employed, US and MRI being much more sensitive.

Infants presenting with congenital hypothyroidism and absence of the thyroid gland from its normal location can be scanned using technetium-99m-pertechnetate looking for an ectopic or lingual thyroid (Figure 18.15).

COMPUTED TOMOGRAPHY

CT remains an established and vital imaging modality in pediatrics but has relatively limited application in the newborn, where ultrasound and MRI have many

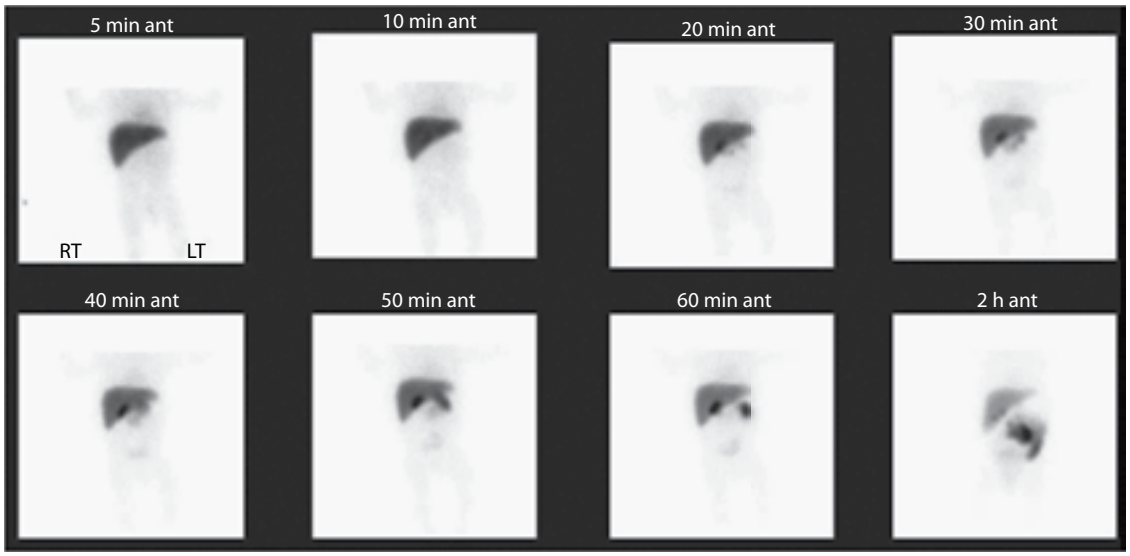

Figure 18.13 HIDA. Radioisotope rapidly appears within the liver. In this normal study, radioisotope is rapidly excreted into the gallbladder (20 minutes) and proximal small bowel (30 minutes). The delayed image at 2 hours shows radioisotope having largely passed through the liver and appearing within small bowel loops (RT = right, LT = left).

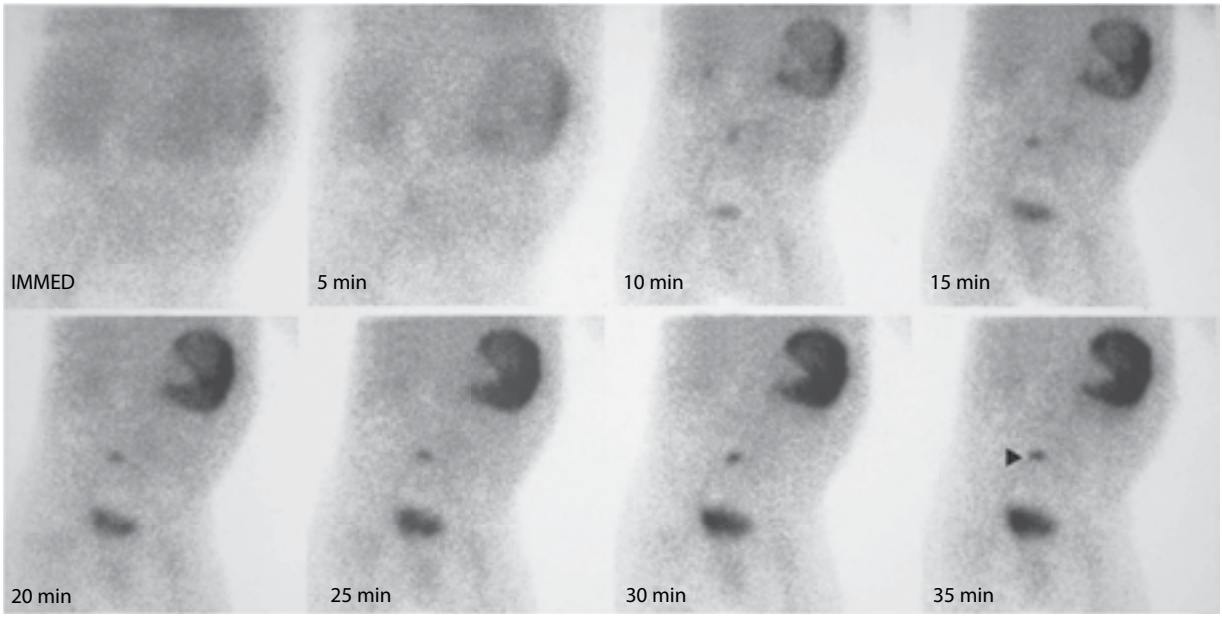

Figure 18.14 Meckel scan. Radioisotope is taken up by gastric mucosa within a Meckel diverticulum (arrowhead). Note the normal uptake by the gastric mucosa of the stomach. Also note the normal appearance of radioisotope within the bladder, having been excreted by the kidneys.

advantages. While CT can be useful in evaluating structural abnormalities in the thorax, such as congenital pulmonary adenomatoid malformations (CPAM) and congenital lobar emphysema (CLE), its usefulness in evaluating the neonatal abdomen is significantly limited by the lack of intra-abdominal fat. In general, abdominal MRI is more useful than CT when US fails to provide the diagnosis. While modern multislice scanning should be available on site in any specialized pediatric unit, radiation dose remains a major concern.[9] CT should be reserved in the newborn for specific indications where other modalities fail to provide sufficient information. These would include cranial CT scans in suspected head trauma; exclusion of intracranial calcification in congenital infection; and assessment of bony abnormality associated with severe choanal atresia (Figure 18.16). In all instances, protocols to reduce radiation dose must be in place as per the ALARA principle.[10]

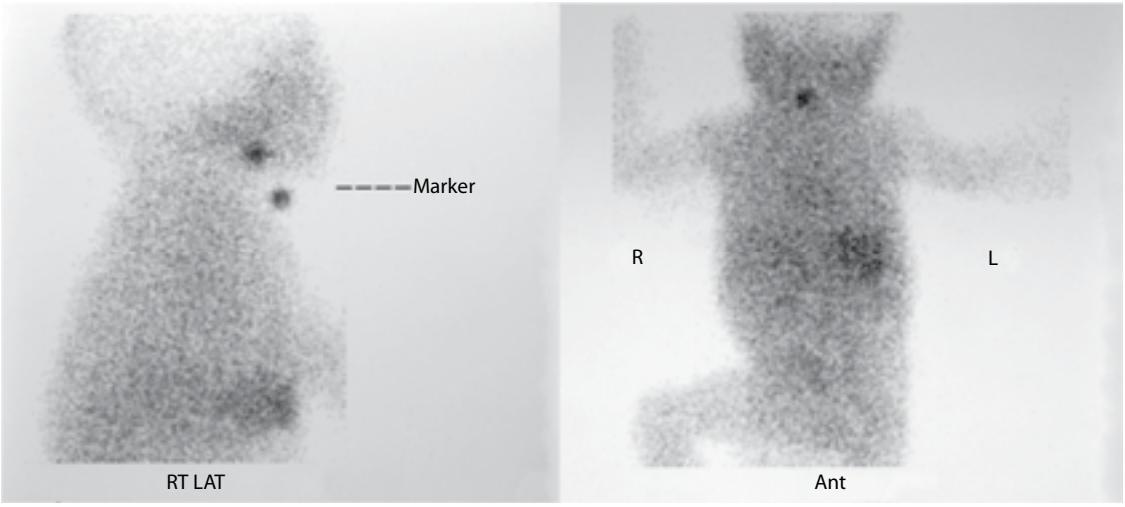

Figure 18.15 Lingual thyroid. Radioisotope accumulates within thyroid tissue, which is located at the base of the tongue. Its position can be determined relative to the chin and the marker at the sternal notch. On the anteroposterior view, the lingual thyroid has a rounded configuration, as opposed to the typical bilobed appearance expected of a normal thyroid gland.

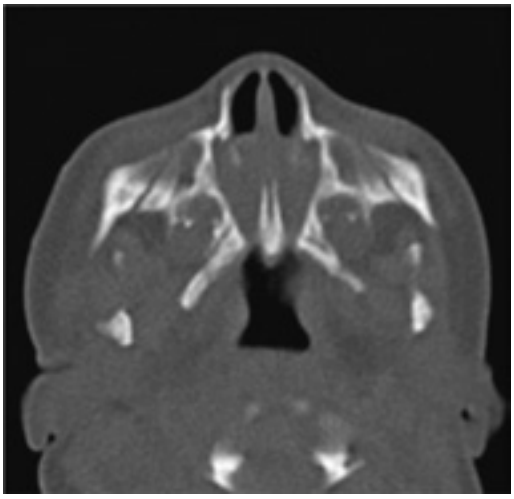

Figure 18.16 Computed tomography (CT) of choanal atresia. CT is the best modality for assessing the bony narrowing of the choanae. In this case there is severe bilateral narrowing of the posterior nasal cavity in a patient with bilateral choanal atresia.

MAGNETIC RESONANCE IMAGING

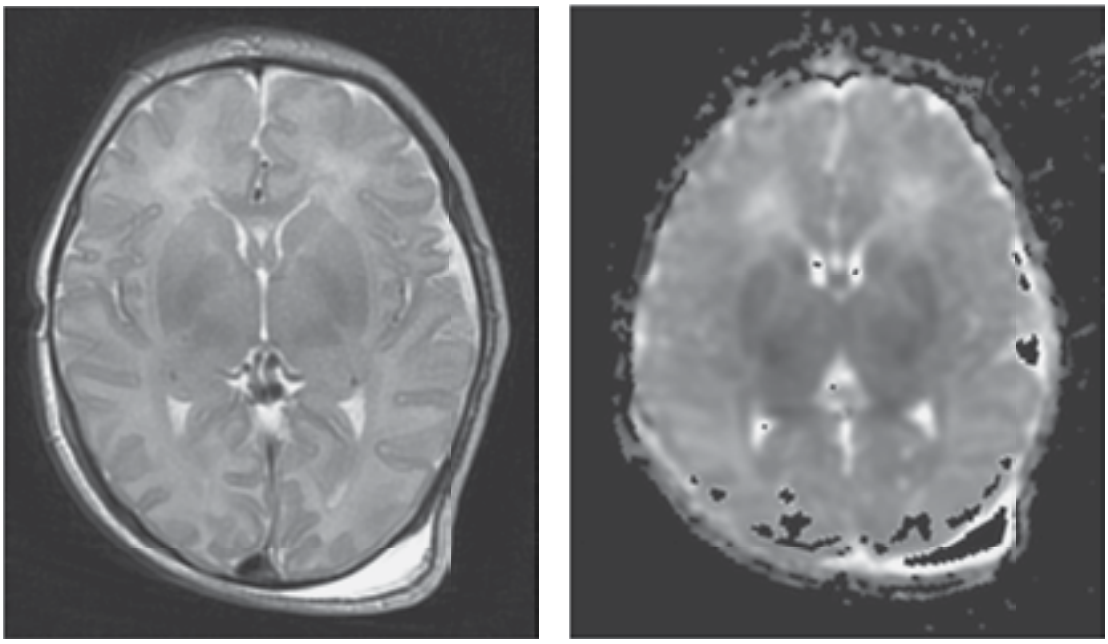
Increased access to MRI has transformed neonatal radiology. While US remains the mainstay of brain and spinal imaging in the neonate because of portability etc., MRI is used to clarify complex malformations and to provide vital functional and prognostic information. Hypoxic–ischemic brain injury (HIE) is a frequent and significant problem in the neonatal period. Regardless of the type of hypoxic injury, the imaging manifestations are related to the gestational maturity of the infant. Hypoxic injury to the premature brain affects primarily the germinal matrix and periventricular white matter, while in the term infant, damage to the cortical tissues and basal ganglia occurs (Figure 18.17). MRI with diffusion weighted imaging and spectroscopy is the diagnostic modality of choice in suspected neonatal HIE.[11]

Outside the central nervous system, the use of MRI is also increasing. In the evaluation of mass lesions of the neck and mediastinum, it offers exquisite anatomical detail. The ability to image in multiple planes facilitates surgical planning. In the abdomen, while US mostly reigns supreme, MRI is increasingly used to evaluate complex masses, to complement US in the biliary tract (magnetic resonance [MR] cholangiography), and to evaluate the renal tract (MR urography). However, its utilization continues to be limited by factors such as cost, availability, and motion artifacts, and in particular by its requirement of sedation or anesthesia.

Recent advances in MRI technology allow safe and accurate imaging of the fetus. Fetal MRI has become a useful adjunct to antenatal ultrasound.[12] It plays an important role in further evaluation of complex intracranial abnormalities. It is increasingly utilized in the antenatal assessment of complex thoracic and abdominal congenital abnormalities, such as congenital diaphragmatic hernia (CDH), where assessment of the severity of associated pulmonary hypoplasia, using volumetric lung measurements, can be useful in predicting fetal outcome. This information informs difficult decisions regarding management during pregnancy and following delivery. Figure 18.18 is a sagittal MRI scan showing a significant portion of the liver lying within the right hemithorax in a fetus with a right-sided CDH. Figure 18.19 shows MR imaging of a fetus with a large cystic hygroma of the neck. Assessment of the extent of the lesion, in particular its relationship to the airway, allowed planning for the EXIT procedure.[13]

INTERVENTIONAL TECHNIQUES

There has been a dramatic increase in recent years in the number, range, and complexity of interventional procedures



(a) (b)

Figure 18.17 Magnetic resonance imaging of hypoxic–ischemic brain injury. **(a)** Axial T2 and **(b)** adjusted diffusion coefficient (ADC) map from the diffusion-weighted imaging (DWI). Signal abnormality in the newborn is often subtle on T1 and T2 imaging, and is influenced by gestation. DWI, when performed within an appropriate timeframe, is helpful in determining the extent of abnormality. In this term infant, extensive restricted diffusion is clearly evident within the basal ganglia (low signal on the ADC), in keeping with a profound hypoxic–ischemic event.

in pediatric as well as in adult radiology practice. Hospital stay may be shortened and patient outcome improved as these interventional procedures tend to be more cost-effective than the alternative conventional surgical approach. In the gastrointestinal tract, hydrostatic or pneumatic reduction of intussusception is a well-established technique. This, however, is a rare condition in the newborn. The nonoperative management of meconium ileus by gastrografin enema is almost universal (Figure 18.20). However, possible complications such as volvulus, peritonitis, and perforation must be excluded before an enema is attempted. The fluoroscopy room should be warm, the infant well hydrated, and a functioning intravenous (IV) line in place. This author advocates the use of diluted gastrografin, one part contrast and two parts water, in order to reduce the risks of mucosal damage. Several attempts may be made over a period of days if the infant's condition permits.

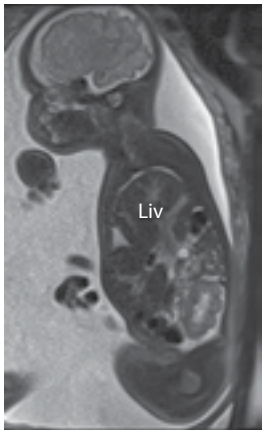


Figure 18.18 Fetal MRI of right CDH. Sagittal T2-weighted image shows a significant portion of liver (Liv) in right hemithorax.

Balloon catheter dilatation of postanastomosis esophageal strictures in neonates following repair of esophageal atresia is now established in major centers worldwide. The advantages of balloon dilatation over bougienage relate to the marked reduction in shear force with radial force mainly achieving the dilatation.

Balloon dilatation of colonic strictures complicating necrotizing enterocolitis is another useful, though infrequent, interventional procedure. Percutaneous gastrostomy and placement of a feeding tube in the jejunum are further useful techniques performed under fluoroscopy.

In urinary tract obstruction, percutaneous nephrostomy to relieve obstruction is widely practiced and should be performed under direct US guidance. Either a single-stab technique or a modified Seldinger approach may be used, and a pigtail catheter is left in place.

Percutaneous biopsy of organs or lesions under ultrasound, fluoroscopic, or CT guidance and the aspiration or drainage of abscesses or cysts are all part of the interventional radiologist's workload. The cumulative radiation burden to the infant must be borne in mind, and in general, ultrasound is the imaging modality of choice.[14]

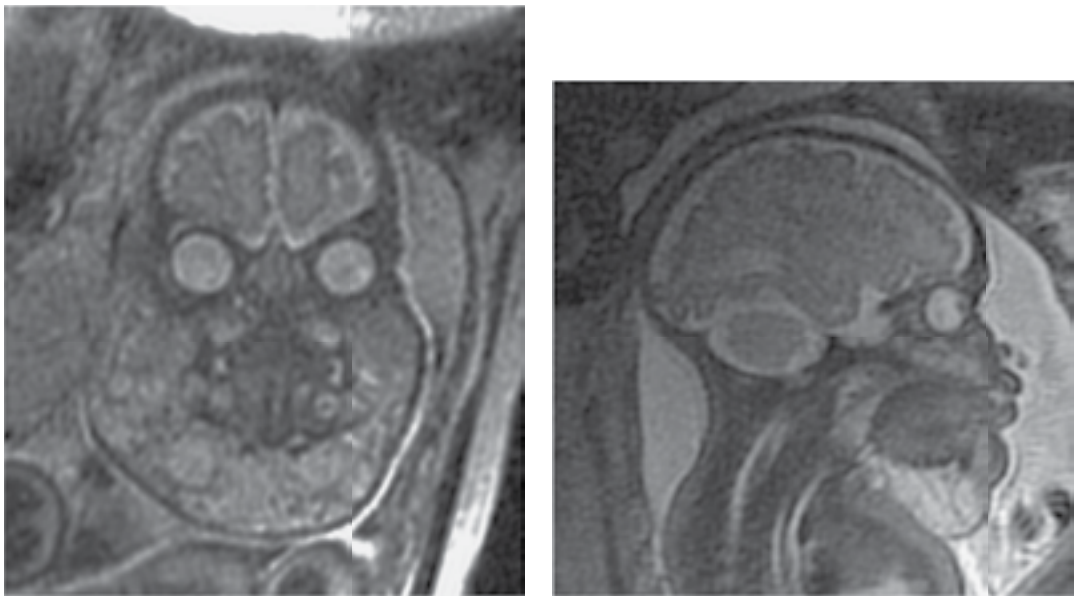

Figure 18.19 Magnetic resonance image (MRI) of fetus with a large cystic hygroma involving the floor of the mouth. Coronal and sagittal T2-weighted images showed the extent of this high-signal mass, and it's relationship to the airway, and facilitated planning for an elective EXIT procedure.

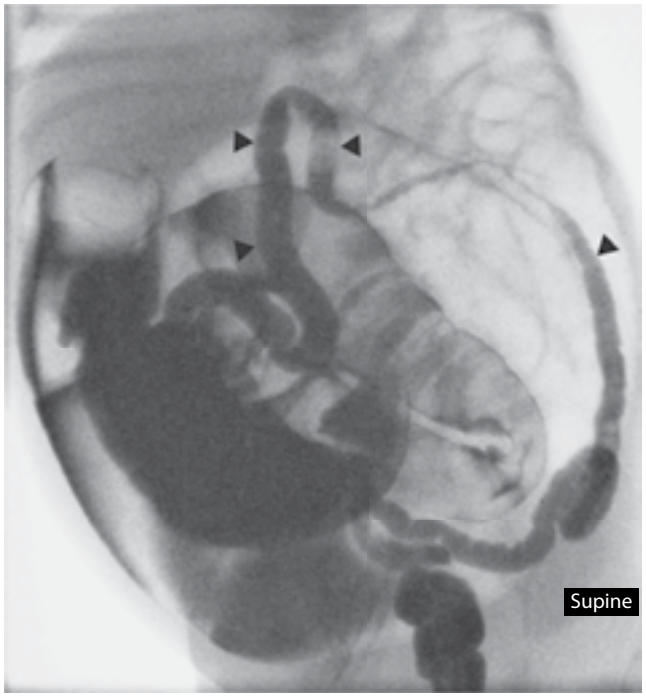

Figure 18.20 Meconium ileus. Contrast enema. Contrast fills a microcolon (arrowheads) before refluxing into markedly distended distal small bowel loops. Filling defects within these dilated loops are due to impacted meconium in this neonate with meconium ileus.

In the very-low-birth-weight (VLBW) infants, vascular access procedures are amongst the most common indications for radiological intervention and are not without complication.[15]

CONCLUSION

The role of the imaging department and of the pediatric radiologist in the management of the neonatal patient is continuously evolving and expanding. They should be involved as integral members of the *team*. Frequent consultation amongst all carers will avoid inappropriate requests for imaging. It will prevent duplication of examinations and the accumulation of redundant information, thus helping to reduce costs. The application of appropriate imaging techniques will also have the great virtue of reducing the infant's discomfort and morbidity.

Immune system of the newborn

JUDITH MEEHAN, MURWAN OMER, FIONA O'HARE, DENIS J. REEN, AND ELEANOR J. MOLLOY

INTRODUCTION

The first line of defense against infection is the innate immune system, and activation occurs when a pathogen breaches the host's natural barriers (Figure 19.1).[1] The innate immune system developed before the separation of vertebrates from invertebrates and is the primary immune response for most multicellular organisms.[2] It responds instantaneously to microbes and is composed of both soluble (the alternative and mannan-binding lectin pathways of the complement system, acute phase proteins, and cytokines) and cellular elements (monocytes, macrophages, neutrophils, dendritic cells, and natural killer cells). Careful modulation of the innate immune system is vital to prevent either uncontrolled microbial growth or devastating inflammatory responses with tissue injury, vascular collapse, and multiorgan failure. Neonatal immunological research has concentrated on umbilical cord blood, and there is a paucity of detailed mechanistic research in neonatal postnatal samples due to the smaller blood volumes available. Recent developments in the analysis of microsamples including microarrays and multiplex assays have allowed rapid advances in the understanding of neonatal immunology during early development.

Detection of invading microorganisms is mediated by pattern recognition receptors expressed on the surface of innate immune cells, which recognize structures common to many microbial pathogens and are called pathogen associated molecular patterns (PAMPs). These include endotoxins (lipopolysaccharide: LPS), peptidoglycan, lipoteichoic acid, lipopeptides, flagellin, mannan, and viral RNA, which are essential for survival of the microorganisms and therefore do not undergo major mutations. Pattern recognition receptors have been evolutionarily conserved not to recognize any self-structure. Any receptor that bound to a self-ligand could lead to death of the organism that expressed such a receptor. Therefore, autoimmunity is prevented when the only available recognition system is the innate immune system.[3]

Several intracellular signaling pathways are activated when a PAMP binds to a pattern recognition receptor, resulting in activation of transcription factors (NF-kB, AP-1, Fos, Jun). These transcription factors control the expression of immune response genes and the release of numerous effector molecules, such as cytokines. Cytokines are chemical mediators with an essential role in orchestrating the innate and acquired immune responses to an invading pathogen.[4]

The acquired immune system has evolved relatively recently and is built upon the phylogenetically older innate immune system, by which it is controlled and assisted. The principal mediators of acquired immunity are the highly evolved lymphocytes, which express an enormous array of recombinant receptors, immunoglobulin and T-cell receptors (TCRs). They can recognize any potential pathogen with which the host may come in contact. This response takes from days to weeks to develop optimally. Newborns acquire passive immunity from their mothers by maternally derived IgG crossing the placenta. Transferable maternal immunologic memory is essential for the survival of the fetus, newborn, and infant. Moreover, the attenuation of infection by transferable maternal immunity permits microbial agents to immunize the child under optimal conditions. This provides protection for up to the first 6 months of life at which time neonatal acquired immunity has developed.[5]

The hygiene hypothesis states that exposure to allergens in the environment early in life reduces the risk of developing allergies by boosting immune system activity. Conversely, relatively clean environment in early life would sway the immune system toward allergy-promoting responses. The hygiene hypothesis may explain the rising incidence of allergic diseases and facts such as the lower incidence of allergy in those living on farms or in rural areas (due possibly to more exposure to bacteria); the lower incidence of allergy in younger children of large families

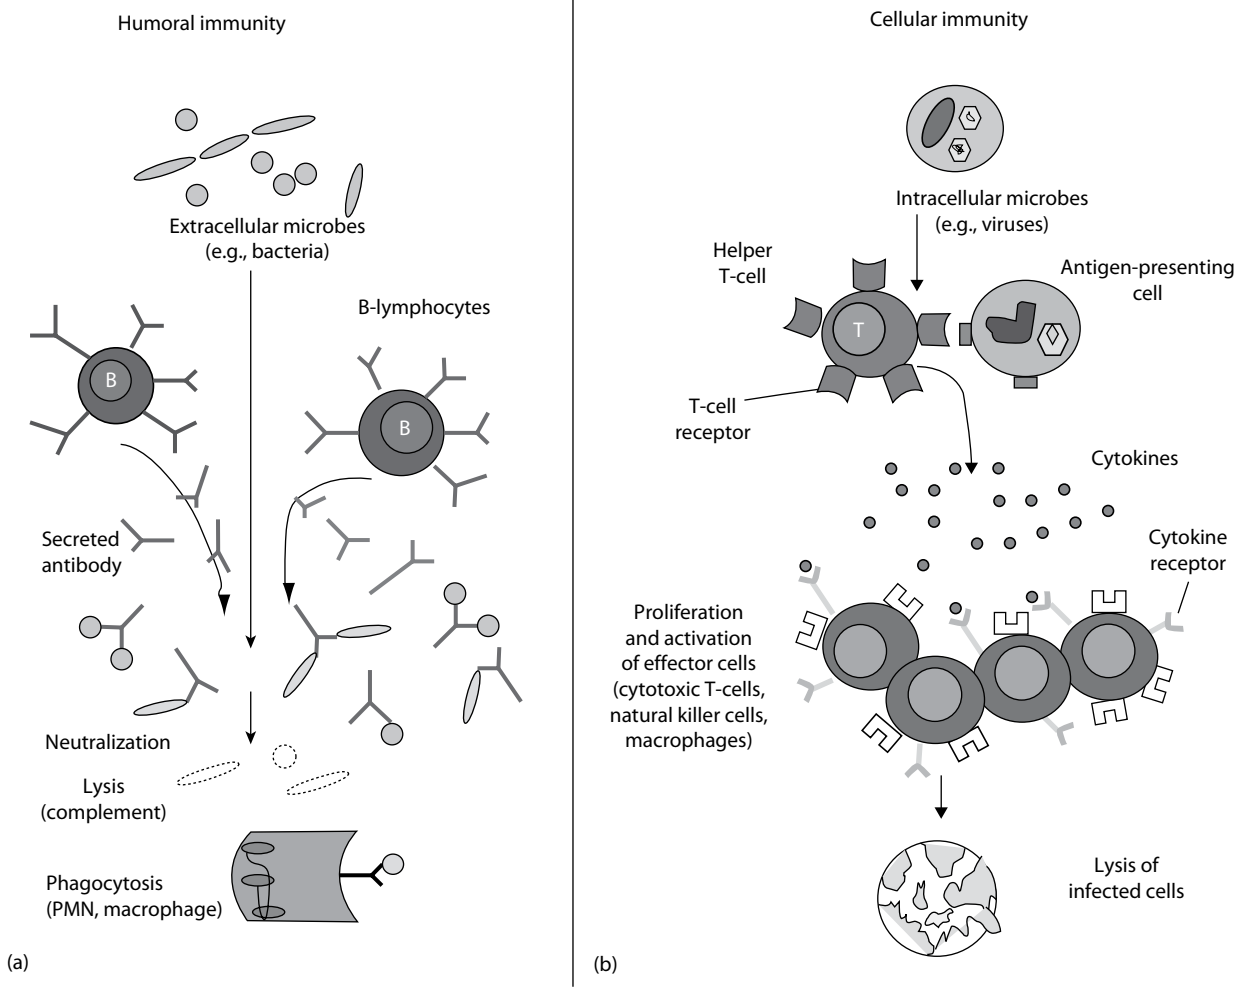

Figure 19.1 Immune function: humoral and cellular immunity. Humoral immunity is mediated by B-lymphocytes, which produce soluble antibody proteins. These antibodies can either **(a)** directly neutralize extracellular microbes or **(b)** activate complement, neutrophils, and macrophages to kill microorganisms. Cellular immunity is mediated by T-lymphocytes. Cytotoxic T-cells directly lyse pathogens. Helper T-cells produce cytokines, which stimulate other immune cells to remove microorganisms.

with three or more older siblings (due perhaps to repeated exposure to infection); and the lower incidence of asthma and wheezing in children attending day care (with more exposure to infections). The hygiene hypothesis, however, cannot explain the higher rates of allergic asthma among poor African Americans in inner city areas.[6,7]

CLINICAL OUTCOMES IN NEONATAL SEPSIS AND INFLAMMATION

Death and long-term complications are common sequelae of bacterial infections in newborns. Neonates undergoing intensive care have infection rates of 25%–50%,[8,9] and mortality has not changed from 15% to 20% over the last 20 years. Altered bactericidal mechanisms are responsible for the increased vulnerability to sepsis in this group and mirror the pattern seen in grossly neutropenic patients.[10] Neutropenia commonly develops in neonatal sepsis in contrast to the leukocytosis in septic adults.[11] This may be mediated by a decreased neutrophil storage pool and a limited capacity for increased progenitor production in newborns especially preterms.[12]

There is increasing evidence that sepsis and inflammation are important in the pathogenesis of perinatal brain injury. In preterm infants, episodes of sepsis are associated with poorer neurodevelopmental outcomes.[13] In addition, an association between cerebral palsy and maternal peripartum infection in term infants has been well documented.[14] Elevated proinflammatory cytokines have also been demonstrated in retrospectively reviewed dried neonatal blood spots from children aged 3 years with cerebral palsy.[15] Activated leukocytes and infection have been implicated in the pathogenesis of neonatal brain damage.[16] Severe disruption of the blood brain barrier in severe asphyxia may exacerbate neuronal damage[17] allowing infiltration of activated immune cells and cytokines.

NEONATAL INNATE IMMUNITY

Newborns rely on their innate immune system initially following birth as there are deficiencies in the adaptive response due to lack of previous exposure to antigens *in utero*.[7] The intrauterine environment is usually sterile, and transition postnatally to the foreign antigen-rich external world starts with colonization of skin and gut with microorganisms. The fetus is considered to be immunologically naive and exists in a state of immune privilege *in utero* to prevent rejection by the maternal immune cells. The *in utero* defense system is largely unknown, although recent evidence hints at a powerful fetal system of innate immunity.[18] The antibacterial properties of vernix caseosa, the creamy white substance covering the skin of term babies, have also been recognized and in particular the presence of antimicrobial peptides including alpha defensins[19] and inflammatory mediators.[20] Antimicrobial peptides may be an adjunctive compensatory mechanism in the neonate as adaptive immunity evolves.[21] Neonates are immune competent but with a predominant Th2 profile being geared toward immune tolerance instead of toward defense from microbial infections (Th1-skewed).[22] Th1 responses are suppressed by placental products such as progesterone, prostaglandin E2, and cytokines such as IL-4 and IL-10.[23–25]

MONOCYTES

The crucial role of monocytes/macrophages in the immune response resides in their accessory cell and immunoregulatory functions of both humoral and cellular immunity. Human cord blood contains almost three times as many monocytes as adult blood, and major changes occur in the levels of monocytes during the first few weeks of life. Newborn macrophages show poor resistance against facultative intracellular organisms. Newborn monocytes exhibit marked heterogeneity with respect to density. This heterogeneity in density is reflected in functional responses in different populations of newborn monocytes.[26] The densest populations of newborn monocytes appear to have helper function for antibody production, while suppressor function resides in the less dense populations.[27] Neonatal blood monocytes are also characterized as having a much lower frequency of class II molecular expression than adult monocytes, which may be related to the selective incapacity of neonates to secrete significant levels of IFN-γ.[28] The precise role of the monocyte in the newborn's unique susceptibility to infections with various agents remains a challenging area for future study. Dendritic cells are the primary antigen-presenting cells for optimum sensitization of naive T-cells to antigen. Newborn dendritic cells have been shown to be deficient in IL-12 (p35) expression, a key regulator of Th1-type T-cell responses.[29]

The innate immune response relies on cell membrane (Toll-like receptors [TLR]) and intracellular (Nod-like receptors [NLR]) sensors to detect invading microbes. On sensing danger signals, some of the NLR can also trigger the activation of IL-1β by forming a large multiprotein complex called inflammasome.[144] The term inflammasome describes the caspase-activating complex that plays a major role in innate immune responses.[145] The NLRP3 inflammasome components are NLRP3 (NLR family, pyrin domain containing 3), ASC (apoptosis-related speck-like protein containing a caspase recruitment domain [CARD]), and procaspase-1.[146]

Sharma et al.[150] demonstrated crucial tight developmental mechanisms controlling IL-1β production by human monocytes in early gestation. While monocytes from preterm cord blood exhibit limited activation of caspase-1, preterm neonate's ability to secrete IL-1β is comparable to adult levels within 2 weeks postnatally, suggesting rapid maturation of these responses after birth.[150]

Neutrophils

The critical role of the neutrophil in host defenses against microbial infection has long suggested that defects in this particular cell type might be the cause of the increased susceptibility of the newborn to serious bacterial infections. Impaired neonatal neutrophil function at birth has also been implicated in neonatal inflammatory disorders.[11] Recent advances in our understanding of the molecular basis of cell adherence and phagocytosis have provided us with greater insight into the role of the neutrophil in the newborn's defense system. Numerous *in vitro* abnormalities include decreased chemotaxis, leukocyte adherence, bacterial killing, and depressed oxidative metabolism.[30,31] However, most of these neonatal neutrophil functions have been found in cord blood, which contains immature forms of the cells, and therefore care must be taken in interpreting some of the data. Oxidative metabolic function of cord blood monocytes, measured by chemoluminescence, has been shown to be depressed 12–36 hours after birth.[32] Cytoskeletal actin polymerization has also been shown to be altered in neonates.[33]

Decreased adherence of neonatal neutrophils may be caused, at least in part, by the decreased expression of adherence glycoproteins, or by decreased fibronectin content in the plasma membrane of neutrophils.[34] Humoral defects have also been found in neonates, which may help explain the decreased levels of chemotaxis reported in neonatal neutrophils. Such altered humoral factors include decreased levels of complement components and fibronectin.[35,36]

Neonatal neutrophils exhibit normal phagocytosis of opsonized particles as well as particles that required no opsonization. The major opsonic role of neutrophils for the uptake of antibody or complement-coated microorganisms is reflected in their expression of a number of receptors both for antibody (Fc-receptors) and complement (CR receptors). In newborn cord blood, the levels of these receptors are similar to those in adult neutrophils.[37–39] The level of expression of Fc receptors is significantly more upregulated in response to *in vitro* stimuli such as f-met-leu-phe (FMLP) on adult neutrophils compared to newborn neutrophils.[33]

Neonatal neutrophils have diminished function[40] and delayed apoptosis (programmed cell death) compared with adults.[41,42] In addition, neonatal neutrophil LPS responses are altered,[43,44] which may further increase susceptibility to sepsis in this population. The effects of granulocyte colony stimulating factor (GCSF) and granulocyte macrophage colony stimulating factor (GM-CSF) on neonatal neutrophils are altered compared with adults showing that GCSF may improve neutrophil survival, whereas GM-CSF augments function.[45]

Neutrophil extracellular traps (NETs) are lattices of extracellular DNA, chromatin, and antibacterial proteins that mediate extracellular killing of microorganisms and are thought to form via a unique death pathway signaled by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase-generated reactive oxygen species (ROS). Neutrophils from term and preterm infants fail to form NETs when activated by inflammatory agonists—in contrast to leukocytes from healthy adults reflecting a deficit in extracellular bacterial killing.[46]

THE INFLAMMATORY RESPONSE SYNDROMES

One reason for the failure of anti-inflammatory strategies in patients with sepsis may be a change in the syndrome over time (Figure 19.2). Initially, sepsis may be characterized by increases in inflammatory mediators; but as sepsis persists, there is a shift toward an anti-inflammatory immunosuppressive state.[47,48] If the initial insult is sufficiently severe, the proinflammatory response can become intense and lead to a massive systemic inflammatory response syndrome (SIRS) and disrupts homeostasis.[49] If the delay is prolonged and the resolution of inflammation is blocked, the neutrophil[50] has a very high potential for causing extreme damage to healthy tissue due to the concentrated release of ROS and proteases.[51] This then forces the body to produce a massive compensatory anti-inflammatory response syndrome (CARS) that may be inappropriate and result in tissue injury. If this occurs, the body develops "immune paralysis" and is more susceptible to infection. The final stage occurs when the overwhelming inflammation is not resolved causing multiple organ dysfunction syndrome and death of the patient.[52] Adjunctive immunomodulatory treatments for sepsis seek to balance these responses and restore homeostasis.[52] However, discovering which inflammatory phase is dominant in the patient at a certain time point remains difficult and hinders appropriate therapeutic immunomodulation. Anti-inflammatory treatment can increase mortality. Following a cecal ligation and puncture model of sepsis in a murine model, mortality was increased in mice pretreated with interleukin receptor antagonist (IL-1ra).[53]

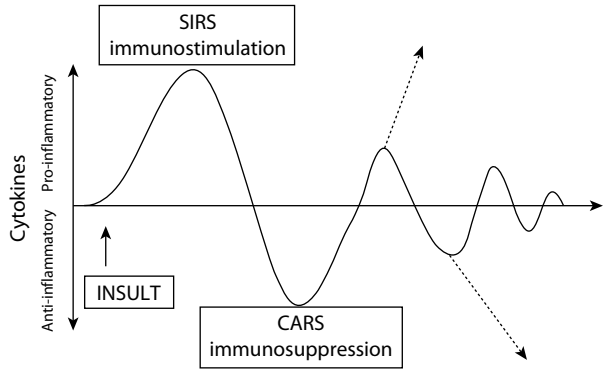

Figure 19.2 Pro-v anti-inflammatory responses. These responses eventually balance to produce homeostasis and recovery. If one or other response predominates, it may increase morbidity and mortality. SIRS: systemic inflammatory response syndrome; CARS: compensatory anti-inflammatory response syndrome.

Fetal and neonatal inflammatory responses (FIRS and NIRS) have been described. A systemic fetal inflammatory response as determined by increased interleukin-6 is an independent risk factor for severe neonatal morbidity.[54] Preterm neonates with systemic infection have elevated IL-6, IL-10, and TNF-α concentrations. Severe infection is signified by increased IL-10/TNF-α, and IL-6/IL-10 ratios. Transiently elevated IL-10 or IL-10/TNF-α levels are not invariably associated with a poor prognosis.[55]

Toll-like receptors

The TLR provide the critical link between microbial immune stimulants and initiation of host defense. TLR-4 is the transmembrane LPS receptor that initiates the innate immune response to common gram-negative bacteria.[56] Neonates have an equivalent if not enhanced capacity compared with adult white-blood cell TLR-mediated response to support Th17- and Th2-type immunity, which promotes defense against extracellular pathogens. However, neonates have reduced Th1-type responses, which promote defense against intracellular pathogens.[57] TLR-4, TLR-2, and CD14 are increased on neonatal immune cells, and cytokine release is decreased to a greater extent than adults with TLR-4 antagonists.[58] During infections, pathogens bind to TLR-4 and CD14 receptors and induce cytokine release, leading to inflammation. Neonatal IL-10 and TNF-α release depends on LPS binding not only to CD14/TLR-4 but also to CD14 associated with another TLR.[58] There is a differential expression of TLR-2 but not TLR-4 in the course of neonatal sepsis.[59] Although decreased levels of MyD88 have been described in neonatal monocytes in response to LPS,[60] there have been few studies on neonatal neutrophils. Wynn et al.[61] have recently demonstrated improved survival following polymicrobial sepsis induced by TLR-4 agonist pretreatment, which enhanced peritoneal neutrophil recruitment with increased oxidative burst production. Similarly, TLR-7/8 agonism also enhanced peritoneal neutrophil recruitment with increased phagocytic ability. However, these outcomes were independent of the adaptive immune system and type I interferon signaling.[61] Labor upregulates TLR-2 and TLR-4 on cord blood monocytes at the protein level, suggesting that labor may

be immunologically beneficial to normal newborns.[62] Augmenting innate immune function using TLR signaling may be a potential future adjunctive therapy in neonatal sepsis.

MUCOSAL IMMUNITY, HUMAN MILK, AND NECROTIZING ENTEROCOLITIS

Although the intestinal tract of the fetus is considered to be sterile, recent studies suggest that many preterm infants are exposed to microbes found in the amniotic fluid, even without a history of rupture of membranes or culture-positive chorioamnionitis.[63] Infants are colonized during vaginal delivery and subsequent breastfeeding with maternal vaginal and fecal flora. The fecal microbial profile of infants delivered vaginally versus caesarean section showed no colonization with *Bacteroides* sp. before 2 months of age in infants in the latter group, and *Bacteroides* colonization that was half that of vaginally delivered infants by 6 months of age.[64] The common use of antibiotics, type of feeding (human milk versus formula), mode of delivery (vaginal versus caesarean section), decreased maternal–infant direct skin contact, and various manipulations in the neonatal intensive care unit (e.g., nursing in an incubator versus under radiant warmers) have the potential to alter the intestinal microbiota.[65] In response to pathogenic intestinal microbiota, proinflammatory cytokines can increase barrier permeability, facilitating bacterial translocation with elaboration of the SIRS and multiple organ failure.[66]

Necrotizing enterocolitis (NEC) is one of the most devastating diseases in newborns. It is associated with loss of gut integrity and immune dysfunction. NEC is also characterized by exaggerated TLR-4 signaling and decreased enterocyte proliferation through unknown mechanisms.[67] Delayed bacterial commensal gut colonization is common in preterm infants in intensive care and tends to render bacterial species virulent. This abnormally upregulates TLR-4 and is associated with activation of NF-kappa-B, promoting the transcription of genes for inflammation, and increased concentrations of inducible nitric oxide synthase, another potent proinflammatory regulator.[68] Increased intestinal expression of TLRs (especially TLR-2 and -4) and cytokines precedes histological injury in the experimental NEC.[69]

There is a dose-related association of human milk feeding with a reduction of risk of NEC or death after the first 2 weeks of life among extremely low birth weight infants.[70] Human milk influences neonatal microbial recognition by modulating TLR-mediated responses specifically and differentially.[71] Fresh human milk contains many immunoprotective factors, such as immunoglobulins (Igs), lactoferrin, neutrophils, lymphocytes, lysozyme, and PAF acetylhydrolase (which inhibits PAF). Human milk also is believed to promote intestinal colonization with *Lactobacillus*. The efficacy of banked human milk is less clear because freezing and pasteurization reduce the cellular components and immunoglobulins.[66]

NEONATAL ADAPTIVE IMMUNE RESPONSE

The adaptive immune system consists of B-cells, T-cells, and their products. T-cells or lymphocyte clones each bears a unique TCR that recognizes peptides, derived from foreign or self-proteins, bound in a molecular complex to the major histocompatibility complex (MHC) proteins on the surface of other cells. T-cells are divided into subsets based on their expression of different proteins, which are assigned cluster differentiation (CD) numbers. Killer T-cells express CD8 and are important to kill virally infected cells. Helper T-cells express CD4 and orchestrate the overall immune response by secreting cytokines and providing costimulatory signals to CD8+ cells and B-cells.

The basis of an adequate immune response resides in the capacity of individual cells of the immune system to recognize and react to the myriad of antigens in the environment. The hemopoietic system of pluripotent stem cells is the source of all the major cell types, which are involved in the immune response. These cells include various lymphocyte subsets, macrophages, natural killer cells, monocytes, and polymorphonuclear leukocytes. These cells are involved in a complex regulatory network of cell interactions, which constitute an immune response, and whose function is to eliminate both self-aberrant molecules and cells, as well as to protect the host from microbial attack (Figure 19.3).

Lymphocyte development occurs along two distinct pathways leading to the production of the two major lymphocyte populations, T-cells and B-cells, which have very different biological effector functions. The thymus is the site of development of T-cells, which are responsible for the range of effector functions collectively termed cell-mediated immunity. Cell-mediated immunity ranges from the release of soluble factors such as cytokines, which regulate the activity of all cells of the immune system, to direct cytopathic effect of cytotoxic lymphocytes on viruses or tumor cells. B-lymphocytes, on the other hand, have a more restricted effector function, confined to the synthesis and secretion of humoral antibodies in each of the immunoglobulin classes, IgG, A, M, D, and E. More recently, B-lymphocytes have been shown to be capable of presenting antigen to T-cells.[72] In man, the site of synthesis of B-lymphocytes is the bone marrow.

The different regulatory and effector functions mediated by cells of the immune system represent the capabilities of populations of cells that can be recognized by the presence of different patterns of expression of cell-surface antigens. The availability of monoclonal antibody reagents for the recognition of lineage, differentiation stage, activation phase, and effector function of different cell types has contributed enormously to our understanding of the extent of heterogeneity of different cell types within the immune system. This heterogeneity of cell types forms the basis for an international leukocyte typing classification system (CD), utilizing monoclonal antibodies that recognize specific cell-surface markers in order to define individual leukocyte subsets.[73]

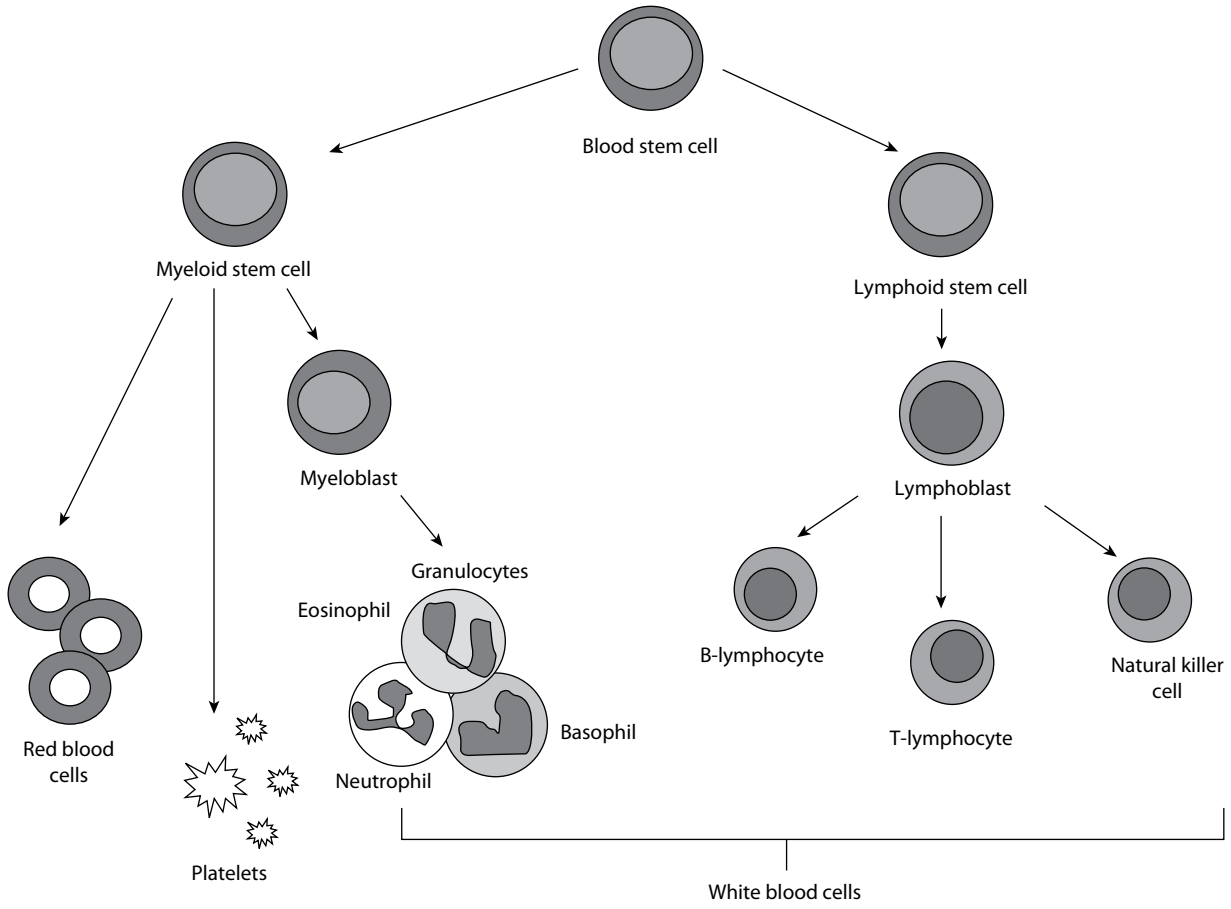

Figure 19.3 Blood cell development. Blood stem cells released from the bone marrow develop into mature blood cells over time. The blood stem cell may become a myeloid stem cell or a lymphoid stem cell. The myeloid stem can further differentiate into either red blood cells, white blood cells, or platelets. The lymphoid stem cell becomes a lymphoblast, which then differentiates into one of the following lymphocyte types: B-lymphocyte, T-lymphocyte, or natural killer cell.

The more widely used CD antigens, for classifying immune effector cell types, are described in Table 19.1.

It is now well established that T-lymphocytes do not recognize native antigen on any pathogen, but rather a processed form of the antigen, in association with self-major histocompatibility antigens (MHCs), or class I (HLA-A,B,C) or class II (HLA-DR/Ia) molecules.[74,75] This important processing of foreign antigen is carried out by one of a group of antigen-presenting cells which include macrophages, dendritic cells, Kupffer cells, and some B-cells. The proper functioning of these accessory cells is therefore as central to an adequate immune response as that of specific effector cells, such as the T-lymphocytes. When antigen becomes localized and processed by the antigen-presenting cell (APC), the complex interaction of APC, T-cells, and B-cells begins, which eventually leads to specific immunological memory, both of T-cells and B-cells, as well as to antibody production. Although B-cells can be directly activated by antigen, under experimental conditions, concomitant activation of T-cells is required for the clonal expansion of antigen-specific B-cells, leading to the generation of long-lived memory B-cells and immunoglobulin-secreting plasma cells.[76,77] In spite of their precipitous encounter with the environment, newborn infants cannot readily mount T helper type 1 (TH1) cell antibacterial and antiviral responses. Instead, they show skewing toward TH2 responses, which, together with immunoregulatory functions, are thought to limit the potential for inflammatory damage, while simultaneously permitting intestinal colonization by commensals. However, these collective capabilities account for relatively few T-cells.

T-cell responses

Several studies in the literature have questioned the stage of maturity of circulating lymphocytes in the newborn. Some parameters of T-cell function in cord blood, however, have been shown to be normal or similar to those of healthy older children. These include the quantity and proportion of T-lymphocytes,[78] lymphocyte response to mitogens,[79] and production of certain cytokines such as IL-2.[80] However, other newborn cellular immune functions have been reported to be depressed. These include PHA-induced cytotoxicity, lymphotoxin production, as well as reduced cAMP

Table 19.1 Cell surface antigens that identify leukocyte subtypes in the newborn

Antigen	Function
T-Cells	
CD2	LFA-3 receptor (adhesion)
CD3	Associated with cell receptor
CD4	Class II and HIV receptor
CD5	Costimulatory
CD7	Unknown
CD8	Class I receptor
B-Cells	
CD19	Signal transduction
CD20	Unknown
CD21	C3d and EBV receptor (CR2)
CD72	Ligand for CD5
NK Cells	
CD16	IgG receptor (FcRIII)
CD56	Isoform of N-CAM
CD94	Unknown
Myeloid/Monocytic Cells	
C14	Unknown
C15	Unknown
CD32	IgG receptor (FcRII)
CD35	C3b receptor (CRI)

levels.[81–83] The overall characteristic that distinguishes newborn T-cells from other T-cells at different stages of development is that they are recent thymic emigrants, not long after exiting the thymus.

Lymphocyte phenotype

There has been a reported incidence of up to 25% of cord blood lymphocytes coexpressing both CD4 helper T-cell and CD8 suppressor T-cell surface markers.[84] Cells of this double positive phenotype are common in the thymus, where they are considered to be the precursors of mature helper and suppressor T-cells. However, more recently, using more sensitive flow cytometry-based analytical techniques, workers investigating cord blood samples failed to detect the presence of doubly labelled CD4/CD8-labelled cells.[85] Other markers of an immature phenotype of newborn T-cells have been described. The CD38 antigen, which is a marker of immature thymus-derived T-cells, as well as activated lymphocytes, is present in the majority of newborn cord blood lymphocytes.[86] This thymocyte-like membrane phenotype can be modulated by the influence of thymic hormones *in vitro*.[87] In addition to the presence of CD38 thymocyte-associated antigen, human cord blood contains T-cells of the unusual phenotype, which include peanut agglutinin-positive/CD8-positive as well as some CD3-positive and CD1a-positive lymphocytes.[88] Like CD38, CD1a is a marker present on early thymocytes.[88] CD1a-positive cells are especially present in preterm and antenatally stressed infants.[89] While the neonate has adequate numbers of CD4 helper T-cells, cord blood T-cells are deficient in their ability to provide help for antibody production, probably at the level of altered cytokine production.[90,91] The cellular basis for this functional defect is reflected in other phenotypic markers of functional activity. More than 90% of cord blood T-cells carry the CD45RA+ "virgin" cell phenotype marker, compared with 50% of adult T-cells, which express CD45RA+.[86] In contrast, less than 10% of cord blood lymphocytes express the CD45RA "memory" T-cell marker compared to a 50% level of expression in adult T-cells.[92] This major imbalance in the ratio of CD45RA+/CD45RA, CD4-positive T-cells in the newborn compared to adults may help explain some of the functional differences of newborn cells compared to adult lymphocytes.

A major T-cell effector function in human newborns is interleukin-8 (CXCL8) production, which may activate antimicrobial neutrophils and γδ T-cells. CXCL8 production was provoked by antigen receptor engagement of T-cells that are distinct from those few cells producing TH1, TH2, and TH17 cytokines, and was costimulated by TLR signaling. This was present in preterm infants especially those with neonatal infections and severe morbidities.[151] However, CXCL8-producing T-cells are infrequently found in adults, and no equivalent function was evident in neonatal mice. CXCL8 production counters the widely held view that T-lymphocytes in very early life are intrinsically anti-inflammatory, with implications for immune monitoring, immune interventions (including vaccination), and immunopathologies. This also highlights the qualitative differences among adult, cord, and neonatal immune function. Regulatory factors contributing to the differences in functional activity and the different phenotypic profiles of newborn T-cells compared to adults require further investigation in order to arrive at a fuller understanding of the mechanisms involved and using actual neonatal postnatal samples rather than cord blood.

B-cell responses

The newborn's capacity to produce antibody is significantly reduced, both quantitatively and qualitatively, compared to that of an adult. Newborn B-lymphocytes poorly differentiate into immunoglobulin-producing cells.[93,94] The mechanisms controlling this aspect of B-cell immunocompetence in the newborn are unknown. Many studies have focused on the ability of cord blood lymphocytes to terminally differentiate into IgG-, IgA-, and IgM-producing plasma cells in response to mitogens. However, a delay occurs in B-cell differentiation, resulting in decreased production of plasma cells, markedly diminishing the secretion of antibody, and restriction of secreted antibody to IgM isotype.[95] Cord blood B-lymphocytes, unlike adult B-cells, usually are unable to differentiate into immunoglobulin plaque-forming cells

when cultured with pokeweed mitogen alone, or with killed *Staphylococcus aureus* Cowan 1 alone.[96] However, it appears that these two stimuli can act synergistically to induce a significant *in vitro* plaque-forming cell response in cord blood B-cells.

The relative inadequacy of IgG and IgA antibody synthesis cannot be attributed to the lack of precursor B-cells, since lymphocytes bearing these immunoglobulin classes on the surface are present in the fetus and on cord blood B-cells.[97,98] The impaired capacity to undergo IgG or IgA synthesis has been attributed to immaturity of cord blood B-cells, since their activation by polyclonal activators, like pokeweed mitogen, LPS, or Epstein–Barr virus, generally results in moderate or reduced levels of IgM synthesis with no IgA, IgG, or IgE production.[94] However, the question of T-cell immaturity as a significant factor in the restricted immunoglobulin isotype production of cord blood B-cells has to be taken into account.[99,100] Cord blood mononuclear cells produce normal levels of IgE *in vitro*, when cultured in the presence of IL-4, indicating that the B-cells are mature in their capacity to switch to IgE-producing cells.[99] The defect observed may be associated with the failure of cord blood T-cells to produce detectable levels of IL-4, which has been shown to be responsible for induction of IgE synthesis, both *in vitro* and *in vivo*.[100] An inadequacy of newborn T-cell help for plasma cell isotype switching to IgG and IgA immunoglobulin-producing cells is also suggested by the observation that IgG and IgA antibody responses are more dependent upon T-cell help than are IgM responses. In a series of experiments, coculturing adult T-cells and newborn T-cells with adult or newborn B-cells, the addition of adult T-cells greatly enhanced the pokeweed mitogen-driven responses of newborn mononuclear cells, which included IgG and IgA responses.[94,101] Cord blood T-cells, however, did not show augmentation of B-cell differentiation when cocultured with non-T-cells from adults. These data, looked at collectively, would indicate that deficient T-cell function as well as possible deficiencies of B-cell function exist in the newborn. The defect in immunoglobulin production may also be contributed, of course, by suppressor T-cell activity of newborn lymphocytes or even by enhanced suppressor activity of newborn monocytes. The newborn also possesses a major population of CD5-positive[94] B-cells, which are only commonly found in patients with autoimmune diseases. It appears that these cells, in the newborn, uniquely express the activation antigens 4F2 and CD25.[102] The significance of these activated CD5-positive B-lymphocytes is, however, unclear. A particular function of these cells is the production of natural polyspecific autoantibodies.[103] A possible role for these cells in the newborn may therefore be the influencing of emerging B-cell specificities. Preterm infants are susceptible to viral infection, and this is associated with impaired Toll-like receptor-3 and -7 expression on gamma delta cells compared with term babies, and they failed to optimize cytokine production in response to coincident TCR and TLR agonists.[104]

IMMUNOGLOBULINS

The presence of physiological hypogammaglobulinemia has been noted by several investigators in preterm and term infants. Neonates have low levels of IgA and IgM immunoglobulins because of the poor ability of these immunoglobulin classes to cross the placenta.[105] Furthermore, all IgG subclasses are not equally transferred across the placenta, especially the IgG2 and IgG_4 subclass levels, which are therefore also relatively low in the newborn.[54] The neonate is consequently very susceptible to pyogenic bacterial infections since most of the antibodies that opsonize capsular polysaccharide antigens of pyogenic bacteria are contained in the IgG2 subclass and IgM immunoglobulin subfraction. Neonates, even during overwhelming sepsis, do not produce type-specific antibodies.[57,106] This impairment in antibody production appears to be secondary to the defect in the differentiation of B-lymphocytes into immunoglobulin-secreting plasma cells and T-lymphocyte-mediated facilitation of antibody synthesis. There is a marked limitation in infant antibody responses to most bacterial capsular polysaccharides.[107] This limitation prevents successful infant immunization with Hib polysaccharide vaccines,[108] which fortunately can be circumvented by use of conjugate vaccines shown to be immunogenic in infants.[109]

CYTOKINES

Among the major molecular components of the immune system are the immunoglobulins, cytokines, and proteins of the acute phase response and complement system. The term "cytokine" is used to describe a group of peptides with potent immunoregulatory effects, which are produced and utilized by individual cells of the immune system, to communicate with each other and to control the environment in which they operate. A description of some of the major characterized cytokines is listed in Table 19.2.

Cytokines are of immense importance in controlling both local and systemic immune responses, inflammation, and the regulation of hematopoiesis.[110,111] Their most important function appears to be at the local level, modulating the behavior of adjacent cells in a paracrine fashion,[111] or the cells that secrete them, in an autocrine fashion.[112] In addition, especially in the case of TNF-α, IL-1, and IL-6, cytokines may effect endocrine-like activity on distant organs or tissues.[113] Cytokines have important biological activity, which can be of major clinical benefit, such as stimulation of antimicrobial function, promotion of wound healing, and myelostimulation.[114,115] With such diverse biological function, an exaggerated or prolonged secretion of these peptides may be detrimental for the host. Specifically, aberrant secretion of cytokines, such as TNF-α and IL-1, is thought to be responsible for the hemodynamic changes in the host during septic shock and in cachexia of chronic disease.[116,117] The availability of recombinant DNA techniques to produce cytokines in almost unlimited quantities and the production of specific antagonists such as soluble cytokine

Table 19.2 Cytokines

Name	Principal cellular source	Principal cellular target
IL-1α+β	Macrophages, fibroblasts, endothelial cells	Thymocytes, endothelial cells, neutrophils, T-cells, B-cells
IL-2	T-cells	T-cells, B-cells
IL-3	T-cells	Multipotential stem cells
IL-4	T helper cells	T-cells, B-cells, mast cells, macrophages
IL-5	T helper cells	B-cells, eosinophils
IL-6	Fibroblasts	B-cells, fibroblasts, hepatocytes
IL-7	Stromal cells	B-cells
IL-8	Macrophages	Neutrophils
IL-10	T-cells, activated monocytes	T-cell subsets, macrophages
IL-12	Macrophages	T-cells, NK cells
IL-13	T helper cells	B-cells
TNF	Macrophages, fibroblasts	Many cell types
TNF	T-cells	Many cell types
IFN	Macrophages, fibroblasts	Many cell types
IFN	Fibroblasts	Many cell types
IFN	T-cells, NK cells	Macrophages, T-cells, B-cells
TGF	T-cells, macrophages, platelets	Many cell types
GM-CSF	T-cells, endothelial cells	Multipotential stem cells

receptors and IL-1 receptor antagonists are leading to new and exciting therapeutic potential for these molecules.

Chronic lung disease may be associated with impairment in the transition from the innate immune response mediated by neutrophils to the adaptive immune response mediated by T-lymphocytes. The Neonatal Research Network of the National Institute of Child Health and Human Development recruited 1062 extremely low birth weight infants of whom 606 infants developed chronic lung disease or died. On the basis of results from all models combined, bronchopulmonary dysplasia/death was associated with higher concentrations of interleukin 1beta, 6, 8, and 10 and interferon gamma, and lower concentrations of interleukin 17, regulated on activation, normal T-cell expressed and secreted, and tumor necrosis factor beta.[118]

IMMUNOMODULATION

Neonates especially those preterms are particularly vulnerable to sepsis. Transplacental transfer of immunoglobulins from the mother to the fetus occurs after 32 weeks of gestation, and endogenous production commences at a few months of age. Administration of intravenous immunoglobulin provides IgG that can bind to cell surface receptors, provide opsonic activity, activate complement, promote antibody-dependent cytotoxicity, and improve neutrophilic chemoluminescence. Term neonates have low type-specific antibody and opsonin deficiencies.[39,119,120] Preterm neonates also have severe hypogammaglobulinemia[121] and deficient complement activity.[122,123]

Theoretically infectious morbidity and morbidity could be reduced by the administration of intravenous immunoglobulin (IVIG). Meta-analysis of small trials has suggested that IVIG may reduce the rate of neonatal death, but the Cochrane review could not recommend routine use of prophylaxis against nosocomial infections or for treatment in proven or suspected infection.[124,125] The International Neonatal Immunotherapy Study (INIS) was an international multicenter randomized controlled trial (RCT) studying the use of nonspecific IVIG in addition to antibiotics in babies with suspected or proven sepsis. This study was designed to confirm or refute the hypothesis that IVIG reduces the rate of mortality and major morbidity.[126] At 113 hospitals in nine countries, infants were enrolled if receiving antibiotics for suspected or proven serious infection (n = 3493) and randomly assigned to receive two infusions of either polyvalent IgG immune globulin or matching placebo 48 hours apart. There was no significant between-group difference in the rates of the primary outcome (death or major disability at 2 years of age), which occurred in 686 of 1759 infants (39%) who received IVIG and in 677 of 1734 infants (39%) who received placebo (relative risk: 1.00; 95% confidence interval [0.92–1.08]). Similarly, there were no significant differences in the rates of secondary outcomes, including the incidence of subsequent sepsis episodes. Therapy with IVIG had no effect on the outcomes of suspected or proven neonatal sepsis.[141]

The recently updated Cochrane review of IVIG for suspected or proven infection in neonates including nine studies of 3973 infants showed no reduction in mortality during hospital stay, or death or major disability at 2 years of age in infants with suspected or proven infection,[153] and therefore treatment with IVIG in this context was not recommended.

Infants with chylothorax postoperatively especially post-cardiothoracic surgery with prolonged, large-volume chyle loss have greater secondary immunodeficiency. Treatment with immunoglobulin is often used in this group of patients, although there is a paucity of detailed studies in this area, and Hoskote et al.[152] did not find any differences in infectious outcomes using IVIG.

COLONY STIMULATING FACTORS AND OTHER IMMUNOMODULATORY AGENTS

Neonates often become neutropenic when septic and therefore the use of GCSF and GM-CSF has been studied on this population. The Cochrane meta-analysis of trials has found no significant improvement in outcome when CSFs were used for prophylaxis or treatment of sepsis.[127]

The PROGRAMS Multicentre RCT of Prophylactic GM-CSF to Reduce Systemic Sepsis in Preterm Neonates included 280 infants <31 weeks. When GM-CSF 10 μg/kg/day was administered prophylactically for 5 days, neutrophil counts were higher on days 3–12 than controls. There were no significant differences in sepsis-free survival in infants who are neutropenic at recruitment, the number of infants experiencing one or more episodes of culture-positive sepsis, or survival to discharge. GM-CSF rapidly corrected neutropenia in preterm, growth-restricted neonates. Prophylactic GM-CSF and correction of neutropenia, even when severe, did not reduce sepsis or all-cause mortality.[128] Kuhn et al.[129] recently described a multicenter, randomized, double-blind, placebo-controlled trial of the prophylactic use of GCSF in neutropenic preterm infants <32 weeks (n = 200) and found no differences in survival free of confirmed infection for 4 weeks after treatment with either rG-CSF (10 mg/kg/day) or placebo for 3 days. However, activated leukocytes may mediate neonatal brain injury.[16] GM-CSF stimulates neonatal neutrophil activation unlike GCSF, and both prolong neutrophil survival.[45] The 2 year developmental outcomes of the PROGRAMS trial showed no improvement in neurodevelopmental or health outcomes at 2 or 5 years after prophylactic administration of GM-CSF.[142] This cohort of babies had lower developmental scores than expected for gestation. The suggestion of worse respiratory outcomes in the GM-CSF group at 2 years was replicated at 5 years.[155]

The 2003 Cochrane review of CSFs in neonatal sepsis included seven treatment studies of 257 infants and three prophylactic studies of 359 infants. The limited data suggesting that CSF treatment may reduce mortality when systemic infection is accompanied by severe neutropenia should be investigated further in adequately powered trials that recruit sufficient infants infected with organisms associated with a significant mortality risk. However, this has not yet been updated with recent trials.[127] APC (drotrecogin alfa [activated]) decreased death from any cause in patients with sepsis (absolute reduction in RR 6.1%), and there was 1 additional life saved for every 16 patients treated. There was a decrease in coagulopathy (D-dimers) and inflammation (IL-6).[130] The RESOLVE (Researching Severe Sepsis and Organ Dysfunction in Children: A Global Perspective) trial evaluated sepsis for safety, pharmacokinetics, and pharmacodynamics of drotrecogin alfa (activated) in children with severe sepsis.[131] The patients ranged from term newborn to 18 years and similar pharmacokinetic profiles, effects on D-dimer levels, other coagulation parameters, and bleeding rates to PROWESS, although there was more gram-negative sepsis.

Pentoxifylline is a phosphodiesterase inhibitor and immunomodulatory agent. Pammi et al. recently updated the Cochrane review of pentoxyfylline for treatment of sepsis and NEC in neonates. They included six trials and 416 participants and found low-quality evidence suggesting that it could be used as an adjunct to antibiotics in neonatal sepsis and decreased mortality without any adverse effects.[156]

Lactoferrin, a normal component of human colostrum and milk, can enhance host defense and may be effective in the prevention of sepsis and NEC in preterm neonates. The recent Cochrane review of this subject included four RCTs, and evidence of moderate to low quality suggests that oral lactoferrin prophylaxis with or without probiotics decreases late-onset sepsis and NEC stage II or greater in preterm infants without adverse effects. Ongoing lactoferrin trials will provide evidence from more than 6000 preterm neonates and may clarify optimum dosing regimens, type of lactoferrin (human or bovine), and long-term outcomes.[156]

PREBIOTICS AND PROBIOTICS

Prebiotics are unique oligosaccharides that are not absorbed but facilitate colonization by probiotic organisms (bifidobacteria and lactic acid-producing bacteria). Use of probiotics has been shown to decrease the duration and severity of rotavirus-induced diarrhea, allergies to cow milk protein, atopic dermatitis, and some inflammatory intestinal diseases. A relative reduction in the risk of NEC, late-onset sepsis, and mortality has been demonstrated with probiotics (*Bifidobacterium infantis*, *Streptococcus thermophilus*, and *Bifidobacterium bifidum* in one study and *Lactobacillus acidophilus* and *B. infantis* in another).[131,132] A multicenter, double-blind, randomized, controlled trial of the probiotics *B. bifidum* and *L. acidophilus* showed a lower incidence of NEC in the study group than controls; but sepsis was more frequent in the study group,[133] although this difference was not significant on multivariate analyses and none of the affected patients developed sepsis with organisms used as probiotics. There are persistent concerns about the use of probiotics in immunosuppressed infants as there have been reports of preterm infants who had short gut syndrome developing *Lactobacillus* bacteremia while receiving this probiotic bacterium.[134] In adults, another multicenter, double-blind, randomized, controlled trial of probiotics to reduce infections in pancreatitis showed a more than twofold increase in mortality and no reduction in infections.[135] In addition to these immediate concerns about sepsis, the long-term effects of the use of probiotics,

especially in preterm infants in terms of immune modulation in later life, development of immune disorders (such as insulin resistance, diabetes, obesity, and cancer), and neurodevelopmental outcomes are not known. In a recent multicenter, randomized controlled phase 3 study, The Probiotics in Preterm Infants Study Collaborative Group (the PIPS trial), infants born between 23 and 30 weeks gestational age were recruited within 48 hours of birth from 24 hospitals in southeast England. Infants were randomly assigned (1:1) to probiotic or placebo via a minimization algorithm randomization program. The probiotic intervention was *Bifidobacterium breve* BBG-001 suspended in dilute elemental infant formula given enterally in a daily dose of 8.2 to 9.2 $\log_{10}$ CFU; the placebo was dilute infant formula alone. Clinicians and families were masked to allocation. The primary outcomes were NEC (Bell stage 2 or 3), blood culture positive sepsis more than 72 hours after birth, and death before discharge from hospital.

Between July 1, 2010 and July 31, 2013, 1315 infants were recruited of whom 654 were allocated to probiotic and 661 to placebo. Five infants had consent withdrawn after randomization; thus, 650 were analyzed in the probiotic group and 660 in the placebo group. Rates of the primary outcomes did not differ significantly between the probiotic and placebo groups; 61 infants (9%) in the probiotic group had NEC compared with 66 (10%) in the placebo group (adjusted risk ratio 0.93 [95% CI 0.68–1.27]); 73 (11%) infants in the probiotics group had sepsis compared with 77 (12%) in the placebo group (0.97 [0.73–1.29]); and 54 (8%) deaths occurred before being discharged home in the probiotic group compared with 56 (9%) in the placebo group (0.93 [0.67–1.30]). No probiotic-associated adverse events were reported.[143]

The recent Cochrane review that predates the PIPS trial included 24 trials and concluded that enteral supplementation of probiotics prevented severe NEC and all-cause mortality in preterm infants. They strongly supported a change in practice.[157] However, there is a need for comparative studies to assess the most effective preparations, timing, and length of therapy to be utilized. This is especially valid in view of the negative results of the PIPS trial.

IMMUNE DEFICIENCY DISEASES IN THE NEWBORN

Although there are many forms of primary immunodeficiency in the newborn, there are several well-described clinical conditions, two of which we will mention in this chapter. Di George's syndrome (DGS) usually involves a hemizygous microdeletion in the chromosome 22q11.2 region characterized by the triad of conotruncal cardiac anomaly, thymic hypoplasia, and hypocalcemia. The syndrome encompasses a broad spectrum of congenital defects that have varying degrees of severity especially in the degree of immunodeficiency, and the incidence is 1 in 4000 births. Only <1% of patients have severe immunodeficiency, but early identification is essential to prevent and treat life-threatening infections and to plan for immune reconstitution. Immunodeficient DGS patients present with profoundly decreased T-cell numbers (<50/mm^3), depressed T-cell function (as measured by lymphocyte proliferation assays, such as with mitogens), and often concomitantly low Ig levels. These patients are at high risk for the development of disseminated and life-threatening infections with organisms that require an intact cell-mediated immune system for eradication, such as cytomegalovirus, adenovirus, or *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*). Graft-versus-host disease also may be found due to transplacental transfer and engraftment of maternal T-cells, leading to the typical rash and diarrhea seen in other forms of graft-versus-host disease.[137]

Severe combined immunodeficiency (SCID) is a primary immune deficiency with a severe defect in both the T- and B-lymphocyte systems resulting in serious infections within the first few months of life. Newborn screening for SCID is advancing toward pilot trials as early diagnosis improves outcomes and facilitates bone marrow transplantation.[138] Persistent lymphopenia or leucopenia and recurrent infections in neonates warrant further investigation and immunology and infectious disease involvement.

NEONATAL AUTOINFLAMMATORY DISORDERS

Cryopyrin-associated periodic syndromes (CAPS) are a spectrum of autoinflammatory disorders; milder forms include familial cold autoinflammatory syndrome and Muckle–Wells syndrome, while the most severe form is represented by neonatal-onset multisystem inflammatory disease (NOMID), also known as chronic infantile neurologic, cutaneous, and arthritis.[159] CAPS results from gain-of-function mutations in the gene coding for NLRP3, a key component of NLRP3 inflammasome, which precipitates an overproduction of IL-1 beta.[149]

NOMID is essentially a clinical diagnosis, and a genetic diagnosis confirms the presence of NLRP3 germline missense mutations in approximately 60% of patients, while somatic mosaicism accounts for up to two thirds of the remainder (40%).[160–162] NOMID is characterized by persistent inflammation and tissue damage primarily affecting the nervous system, eyes, skin, and joints; patients present within the first few weeks of life with urticarial rash, followed by recurrent episodes of fever, arthropathy, and neurological manifestation such as chronic aseptic meningitis, raised intracranial pressure, cerebral atrophy, mental retardation, and seizures. Other clinical presentations include hepatosplenomegaly, eye inflammation, progressive hearing impairment, bony overgrowth, and short stature.[159–163]

The study of patients with NOMID demonstrated the role of IL1-β overproduction in precipitating inflammation-mediated organ damage and the subsequent resolution of symptoms and end-organ damage prevention with IL-1 blockade.[149,158]

CONCLUSION

In fetal and neonatal life, many aspects of the immune system are different to older children and adults. The molecular and cellular basis for these abnormalities, while partially explained by many of the observations described in this chapter, remains relatively unclear. The prospects for more specific and selective immunological intervention as part of the treatment of the immunocompromised neonate undergoing surgery will benefit enormously from ongoing research into the biological basis of immuno-incompetence of the newborn.

Designing new drugs to neutralize microbial products or block their interaction with a specific receptor on immune cells is an attractive concept.[139] Potential targets include LPS binding protein, CD14, TLR-4, and MD-2 for gram-negative sepsis, and CD14, TLR-2, and TLR-6 for gram-positive sepsis. Monoclonal antibodies against CD14 are being evaluated in phase II studies. Several intracellular signaling molecules such as MyD88 and the mitogen-activated protein kinase are other possible therapeutic targets. However, inactivating molecules that are pivotal to innate immunity can be harmful, as shown by the increased sensitivity to bacterial sepsis in mice with mutations of the Tlr4 gene.[140] Careful selection of patients with severe infections associated with a high probability of death will therefore be essential.

Neonatal sepsis

JAMIE GOLDEN, JESSICA A. ZAGORY, CHRISTOPHER P. GAYER, TRACY C. GRIKSCHEIT, AND HENRI R. FORD

INTRODUCTION

Neonatal sepsis remains one of the most common and potentially preventable causes of mortality and long-term morbidity in the world. Although associated mortality is decreasing, over 400,000 neonates worldwide died from sepsis and other infectious conditions in 2015.[1] Compared with uninfected infants, those who develop infections in the neonatal period are significantly more likely to have adverse neurodevelopmental outcomes at follow-up. These include cerebral palsy, poor vision, delayed psychomotor development, low Bayley Scales of Infant Development II scores on the mental development index, as well as impaired head growth, a known predictor of poor neurodevelopmental outcome.[2] This chapter will examine the definition, epidemiology, pathophysiology, diagnosis, management, and outcome of neonatal sepsis.

DEFINITION AND CLASSIFICATIONS

Sepsis was classically described in the adult patient with a Gram-negative infection who subsequently developed fever, hypotension with poor tissue perfusion, and ultimately multiple organ failure. Subsequently, bench and clinical research demonstrated that a number of initial insults, including significant infection, toxin exposure, severe tissue necrosis, and open burn wounds, were capable of inducing these signs and symptoms. Therefore, the term systemic inflammatory response syndrome (SIRS) was introduced to describe a constellation of inflammatory symptoms that include fever, tachycardia, tachypnea, and abnormal white blood cell (WBC) count. A number of proinflammatory as well as regulatory (or anti-inflammatory) cytokines and hormones have been identified in association with the SIRS response. Investigators have grouped various patterns of cytokine response with specific clinical signs and symptoms. Thus, in addition to SIRS, the concept of a compensatory anti-inflammatory response syndrome (CARS) or a mixed anti-inflammatory response syndrome (MARS)[3,4] has also evolved (Figure 20.1).[5]

Until recently, sepsis was defined as the presence of a SIRS response coupled with a causative infection. The surviving sepsis campaign defined severe sepsis as sepsis plus sepsis-induced organ dysfunction or tissue hypoperfusion, and defined septic shock as sepsis-induced hypoperfusion persisting despite adequate fluid resuscitation.[6] In pediatric patients, these definitions depend on age-specific vital signs and WBC cutoff values. More recently, a task force redefined sepsis in the Third International Consensus Definitions for Sepsis and Septic Shock. Sepsis is currently defined as "life-threatening organ dysfunction caused by a dysregulated host response to infection," thus making the term "severe sepsis" redundant.[7] However, these guidelines, published in 2016, do not specifically address the neonatal population (Figure 20.2).

Neonatal sepsis occurs within the first 28 days of life or up to 4 weeks beyond the expected delivery date in premature infants.[8] It is further subdivided into two categories: early onset sepsis (EOS) and late onset sepsis (LOS). EOS is characterized by the development of sepsis in the first 72 hours of life, while LOS occurs between 72 hours and 28 days of life. EOS and LOS have different etiologies, risk factors, and associated pathogens.

There are multiple criteria for defining or diagnosing sepsis. Clinicians can apply these criteria to determine if sepsis is likely, guide subsequent workup and antibiotic therapy, or document the presence of sepsis for outcome analysis. One of the important early criteria, for example, is the Rochester criteria.[9,10] These criteria predict serious bacterial infection and high risk of sepsis in a population of healthy term infants, less than 3 months of age. However, the Rochester criteria neither effectively define sepsis nor assist in the management of complicated perinatal or preterm infants.[11] Pediatric criteria,[12] developed from large-scale pediatric databases to parallel adult criteria, are useful in defining sepsis for outcome analysis but lack characteristics that

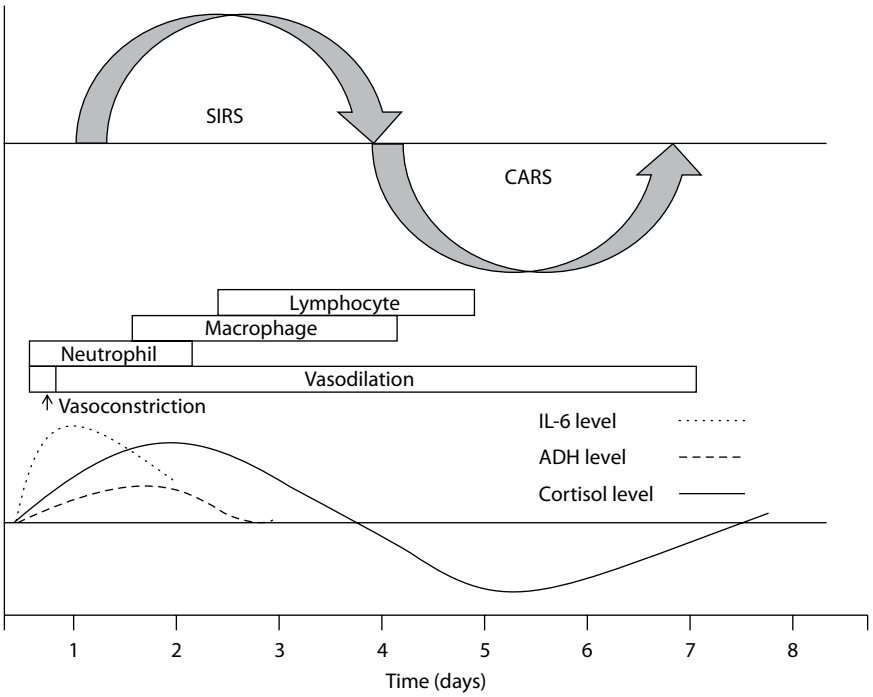

Figure 20.1 Following onset of sepsis, there are predictable phases of systemic inflammatory response syndrome (SIRS) and compensatory anti-inflammatory response syndrome (CARS). This figure is not meant to be comprehensive but representative of several of the most well understood components of each phase.

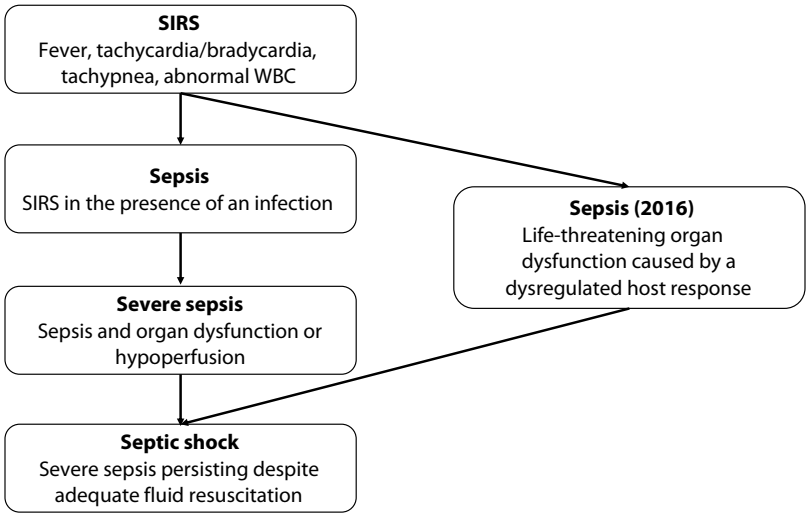

Figure 20.2 Classification of neonatal inflammatory responses including the most recent definition of sepsis. SIRS= systemic inflammatory response syndrome, WBC=white blood cell count.

make it applicable to the neonatal population. In addition, some criteria are strictly biochemical[13] rather than clinical, in contrast to the more classic "Bone" criteria.[14,15] Table 20.1 shows a useful list of criteria that help define the sepsis syndrome in the neonate.[16–19]

EPIDEMIOLOGY

The incidence of neonatal sepsis has increased in recent years, likely due to advances in neonatology, which allow the most susceptible premature and very low birth weight (VLBW) infants to survive the perinatal period. Rates of infection vary by geographic region, available health care resources, and maternal and infant risk factors.[20] Approximately 75% of neonatal deaths globally occur in the first week of life, and most occur in low- and middle-income countries due to lack of resources, limited access to care, and poor hygiene.[21,22] Recent figures for the overall incidence of neonatal sepsis range from 1 to 170 per 1000 live births, and 4 out of 10 neonates with sepsis die or experience

Table 20.1 Criteria for the diagnosis of sepsis in critically ill neonates and children

Physiologic criteria	Laboratory criteria	Biochemical criteria
1. Fever (rectal temperature >38°C), hypothermia (<35.6°C), or increased temperature variability in Isolette	1. WBC count >12,000 cell/cc or <4000 cell/cc	1. Elevated CRP (>3 mg/cc with physiologic symptoms, >10 mg/cc without symptoms)
2. Tachycardia (heart rate > 95th percentile for age)	2. Bandemia (>10% bands)	2. Elevated interleukin-6 (IL-6 >44.4 pg/mL)
3. Tachypnea (respiratory rate > 95th percentile for age) or increasing frequency of apneic events with bradycardia	3. Ratio of immature to total neutrophils (>0.2 for infection, >0.8 for bone marrow depletion)	3. Elevated procalcitonin (PCT >6.1 ng/mL)
4. Hypotension (mean arterial blood pressure <5th percentile for age)	4. Thrombocytopenia (<50,000 per cc)	4. Elevated lipopolysaccharide binding protein (LBP >25 mg/mL)
5. Poor peripheral perfusion (delayed capillary refill or central-peripheral temperature disparity)	5. Metabolic acidosis (pH <7.25 or base excess <−5)	
6. Oliguria (urine output <1 mL/kg/hour after day of life 1)	6. Elevated lactate (>4 mmol/cc)	
7. Poor feeding		

major disability, including significant neurodevelopmental impairment.[23,24]

Rates of neonatal sepsis vary based on gestational age and birth weight (Tables 20.2 and 20.3). The incidence of EOS and LOS increases with decreasing gestational age and is highest in preterm and extreme preterm infants.[25] Birth weight is defined relative to gestational age and is an independent risk factor for a number of outcomes, including neonatal sepsis. However, age-matched birth weight is a confounding variable. Thus, rate of sepsis for non-age-matched birth weight has been reported as well (Tables 20.3 and 20.4). Unfortunately, birth weight does not capture an additional important variable—the trajectory of intrauterine weight gain. A trajectory of normal weight gain for a small for gestational age fetus is significantly less concerning than a sudden change in the trajectory of weight gain for an appropriate weight fetus. Falling off an intrauterine growth curve can indicate either primary placental insufficiency or increased fetal demand due to maternal–fetal infection. Therefore, an abnormal growth curve is concerning for prenatal infection.

The epidemiology of neonatal sepsis differs between EOS and LOS. EOS is typically transmitted from the mother intrapartum through an ascending infection before or during labor. This includes transmission through hematogenous routes, chorioamnionitis, or during delivery through direct contact with or aspiration/ingestion of invasive organisms. The most commonly identified causative organisms are from the maternal vaginal flora. It is estimated that EOS occurs in 1–2/1000 live births and accounts for 9/1000 neonatal admissions,

Table 20.2 Rate of EOS and LOS by gestational age

	Extreme preterm (23–27 weeks)	Preterm (<37 weeks)	Late preterm (34–36 weeks)	Term (>37 weeks)
EOS	Not reported by gestational age	0.56%	0.44%	0.02%–0.35%
LOS	22%–48%	16%	6.3%	1.4%

Table 20.3 Rates of EOS and LOS sepsis by birth weight

	Extremely low birth weight (<1000 g)	Very low birth weight (1000–1500 g)	Low birth weight (1500–2500 g)	Appropriate birth weight (>2500 g)
EOS	Not reported	0.19%–0.59%	Not reported by weight	0.12%–0.66%
LOS	22%–33% mean, (38% 750–1000 g, 48% 500–750 g)	16%–22% mean, (7% 1250–1500 g, 18% 1000–1250 g)	5%–16%	1.4%–5.6%

Note: This table does not take into account large for gestational age (greatest 10th percentile).

Table 20.4 National surveillance and rates of nosocomial infection in neonatal intensive care units

Type of nosocomial infection	PPN	NNIS
BSI/1000 CVC-day	Not reported	8.6%
<1000 g	12.8%	9.1%
>1000 g	4.7%	4.1%
VAP/1000 vent-day	Not reported	2.5%
<1000 g	4.9%	1.5%
>1500 g	1.1%	1.4%
Overall PNA/1000 pt-day	12.9%	Not reported
UTI/1000 pt-day	8.6%	Not reported

Abbreviations: PPN = Pediatric Prevention Network, NNIS = National Nosocomial Infections Surveillance, BSI = blood stream infection, CVC = central venous catheter, VAP = ventilator-associated pneumonia, PNA = pneumonia, UTI = urinary tract infection.

carrying an associated mortality of 3% in term newborns and 16% in VLBW neonates.[26–29] In the United States, approximately 3300 cases of EOS and 400 deaths occur each year.[20]

In contrast, LOS is transmitted via postnatal acquisition from nosocomial or community pathogens.[30] It is much more common than EOS, with a reported incidence as high as 300/1000 neonates, contributing to up to 7% of neonatal intensive care unit (NICU) admissions.[29] Nursery-acquired sepsis has a national incidence of 1.4%, and NICU-acquired sepsis ranges from 5% to 30%, depending on the level of acuity of the unit.[31] It is a major contributor to morbidity and mortality in the NICU.[32] LOS is associated with indwelling devices commonly used in the NICU, including central venous catheters, endotracheal tubes, and urinary catheters (see Table 20.4).[33] Further, VLBW preterm neonates are at high risk of LOS (16%–30%, increasing to almost 50% in neonates <1000 g) and are the most likely to develop infection.[29]

RISK FACTORS

Risk factors for neonatal sepsis can be divided into maternal and neonatal factors (Table 20.5). Maternal contributors are more likely to be involved in EOS than LOS and have been divided into three categories: infection, colonization, and risk factors.[26] Maternal infection is defined as laboratory-confirmed bacterial infection with clinical signs such as peripartum fever. Colonization is characterized as positive reproductive tract or genital bacterial cultures with or without signs and symptoms of infection (such as group B *Streptococcus* or GBS) and can be associated with a 2% chance of developing invasive disease.[20] Risk factors include prematurity (<37 weeks), preterm labor, or prolonged rupture of membranes (>18 hours), and can lead to an increased risk of ascending infection. Low socioeconomic status or a history of an infant with GBS has also been shown to be strongly associated with EOS. Maternal factors are not thought to contribute strongly to LOS, except for prematurity and low birth weight.[34]

Neonatal factors are more commonly associated with LOS and include VLBW, newborn jaundice, intraventricular hemorrhage, prematurity, indwelling catheters and invasive procedures.[30] Alterations of the innate immune response, lack of passively acquired immunoglobulins from the mother, male sex, low Appearance, Pulse, Grimace, Activity, and Respiration (APGAR) scores, neonatal distress, anemia, hypothermia, and metabolic disorders are also considered neonatal risk factors for sepsis.[30]

Risk factors that predispose infants to nosocomial infection include admission to an intensive care unit, lack of enteral feeds, lack of maternal breast milk, indwelling devices, parenteral nutrition, and intestinal surgery or pathology. Additionally, widespread or prolonged use of broad spectrum antibiotics can lead to transmission of opportunistic or drug-resistant pathogens.[8] Hospitalized infants are also at risk of developing fungal infections such as candidiasis. Putative risk factors for such infections include low birth weight (<1500 g), parenteral nutrition, indwelling catheters, lack of enteral nutrition, mechanical ventilation, H-2 receptor antagonists, abdominal surgery, peritoneal dialysis, and exposure to broad spectrum or antenatal antibiotics.[8]

PATHOPHYSIOLOGY, PATHOGENS, AND BIOMARKERS

Sepsis was most recently defined as life-threatening organ dysfunction caused by a dysregulated host response to infection.[7] Therefore, sepsis involves both bacterial virulence and failure of the host defense system.

Bacterial virulence involves the pathogen's ability to adhere to epithelia, invade through the basement membrane into host tissues, and evade the host defense mechanisms. Microbial invasion depends on bacterial fimbriae or pili binding or adhering to host structural proteins or cellular integrins followed by internalization.[35] Bacteria then use different enzymes and toxins to neutralize intracellular, cell-mediated, and humoral host responses. These include enzymes such as hyaluronidase, collagenase, lecithinase, and proteinases, endotoxins such as lipopolysaccharide (LPS), and exotoxins.

Many pathogens that cause neonatal sepsis have been identified. *Escherichia coli (E. coli)* and group B *Streptococcus* (GBS) are the organisms most commonly involved in EOS. Other organisms that have been implicated in EOS include other *Streptococcus* species, *Staphylococcus aureus, Enterococcus* species, Gram-negative enteric bacilli,

Table 20.5 Risk factors for neonatal sepsis

	EOS	LOS
Maternal risk factors	• Bacterial infection • GBS colonization • Peripartum fever • Prematurity • Preterm labor • Prolonged rupture of membranes (>18 hours) • Low socioeconomic status	• Prematurity • Low birth weight
Neonatal risk factors	• Prematurity	• VLBW • Newborn jaundice • Intraventricular hemorrhage • Prematurity • NICU admission • Indwelling catheters • Invasive procedures
Nosocomial risk factors		• Admission to ICU • Lack of enteral feeds • Lack of maternal breast milk • Parenteral nutrition • Intestinal surgery or pathology • Prolonged broad spectrum antibiotics

Abbreviations: VLBW = very low birth weight, ICU = intensive care unit.

Haemophilus influenzae, and *Listeria monocytogenes*.[36] Viral infections can also cause EOS, including herpes simplex virus, enteroviruses, and parechovirus. Rarely, EOS can be caused by fungal pathogens with *Candida* species as the most common causative fungus.[36] In contrast, LOS is most often caused by Gram-positive organisms (70%) followed by Gram-negative organisms (25%) and fungi (5%). Pathogens responsible for LOS sepsis include coagulase negative *Streptococcus* (42%), *S. aureus* (10%), *Enterococci* (9%), GBS (5%), *E. coli* (8%), *Klebsiella* (5%), *Enterobacter* (5%), and *Pseudomonas* (3%).

The neonatal immune system is quite different from that of pediatric and adult patients. An infant's immune system is relatively immature and experiences a period of immunosuppression as it transitions from fetal to neonatal life. It consists of both innate and adaptive components and can generate both humoral and cellular responses (Figure 20.3). However, adaptive immune response requires 5–7 days from delivery for maturity,[30] while normal complement levels and opsonization do not occur until 6 months of life.[37] The adaptive humoral system is dependent on maternal production of antibodies supplied during the peripartum period through placental transfer and during the postpartum period through maternal colostrum and breast milk. Cellular innate and adaptive defense mechanisms are present as early as 13 weeks gestation, but significant production of leukocytes does not occur until nearly the 30th week.[38]

Barrier function of the skin and mucus membranes is also diminished in the neonatal population and is additionally compromised by invasive procedures such as intravenous access, intubation, and indwelling catheters.[36] The intestinal barrier in infants is particularly vulnerable and especially prone to colonization with pathogens leading to gut origin sepsis. The neonatal gut barrier has decreased motility, decreased acid secretion, and low levels of protective mucous, secretory IgA, and

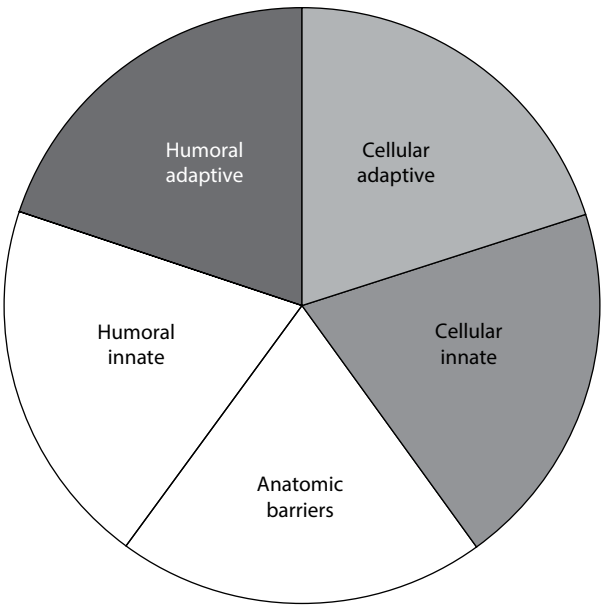

Figure 20.3 Five components of neonatal host defense against pathogens: anatomic barriers including skin and mucosa, innate and adaptive humoral response, and innate and adaptive cell-mediated response.

leaky tight junctions resulting in bacterial translocation from the gastrointestinal tract to normally sterile tissues.[22] Neonates who are delivered vaginally are colonized first with maternal fecal and vaginal flora, while neonates delivered by caesarean section are colonized first with skin flora or bacteria originating from the hospital. However, neonates in the ICU tend to acquire antibiotic-resistant and nosocomial pathogens suggesting that the environment has a strong effect on bacterial flora, patterns of colonization, and susceptibility to gut origin sepsis.[22] Additionally, other internal barriers, such as the meninges and the blood–brain barrier, are immature and allow for active translocation of bacteria to normally sterile areas during bacteremia.[39]

Bacterial invasion followed by stimulation of the host immune response leads to systemic inflammation and production of various inflammatory mediators including cytokines, chemokines, acute-phase proteins, adhesion molecules, components of the complement cascade, and cell surface markers.[40] Cytokines play a central role in neonatal sepsis and can be either proinflammatory or anti-inflammatory. Proinflammatory cytokines such as TNF-α, INF-γ, IL-1β, IL-6, and IL-8 induce a systemic inflammatory response favoring the migration and activation of immune cells. The proinflammatory response is counteracted by anti-inflammatory cytokines, such as IL-10, TGF-β, and IL-4.[40] Acute phase reactants, C reactive protein (CRP) and procalcitonin, are also involved in neonatal sepsis. IL-6 stimulates an increase in CRP concentrations, and levels rise within 6 to 8 hours after inflammation.[41] CRP can be used as a specific and late biomarker of neonatal infection but can also be elevated in noninfectious inflammatory conditions. Procalcitonin is produced by monocytes and hepatocytes 4 to 6 hours after infection.[42] Procalcitonin has a high diagnostic accuracy in the evaluation of neonatal sepsis and has a higher specificity and sensitivity for LOS compared with EOS.[42]

DIAGNOSIS AND WORKUP

Neonatal sepsis can have an extremely subtle initial presentation, and laboratory tests have limited diagnostic accuracy. The first signs of infection in a preterm infant are often apnea, bradycardia, and cyanosis followed by lethargy and increased respiratory effort. A term infant will likely present with respiratory distress.[36] Infants may also present with hyperthermia (>37.8°C) or hypothermia (<36°C), feeding intolerance, or abdominal distention.[8] Physical exam in these infants should evaluate for abnormalities in tone, posture, activity, color, skin changes, tachypnea, and capillary refill. Tachycardia is a nonspecific finding, and bradycardia is often a sign of more advanced sepsis. Meningitis may present with a high pitched cry, abnormal movements, arching of the back, and tense fontanels.[8]

If sepsis is suspected, a thorough history should be obtained to evaluate for exposure to pathogens and risk factors for neonatal sepsis. The Royal College of Obstetricians and Gynaecologists and the National Institute for Health and Care Excellence (NICE) published guidelines focused on the prevention of neonatal sepsis in the United Kingdom. The guidelines were updated in 2012 and include "red flag" indicators that are strongly suggestive of sepsis as well as "non-red flag" risk factors (Table 20.6). Red flags include parenteral antibiotics given to the mother, suspected or confirmed infection in another baby if there is a multiparous pregnancy, respiratory distress starting more than 4 hours after birth, seizures, mechanical ventilation in a term infant, and signs of shock.[43] The NICE guidelines are used to guide further workup and management of neonates with suspected sepsis.

While there are physiologic, laboratory, and biochemical criteria to aid in the diagnosis of sepsis (Table 20.1), the gold standard is a positive blood culture.[44] However, many infants have negative cultures but still have signs of sepsis. These infants may be considered to have "clinical sepsis."[24] Diagnostic workup in sepsis consists of a complete WBC count with differential, blood culture, urine culture, and lumbar puncture (LP) with the addition of tracheal aspirates, acute-phase reactants, and radiographs as indicated (Figure 20.4).

Cultures

One blood culture from a sterile site using at least 1 mL of blood in a single culture bottle is an adequate volume for bacterial detection. Up to 25% of infants with sepsis have low colony count bacteremia, and blood cultures with adequate volume are twice as likely to yield a positive result. Blood is most frequently drawn from a peripheral vein, but a sample from a recently placed umbilical artery catheter is also acceptable.[36,45] Most significant blood cultures are positive by 48 hours.[8]

EOS does not require a urine sample since positive cultures will likely be due to hematogenous seeding of the kidney.[36,45] Urine culture should be considered in older infants and should be from an uncontaminated urine specimen ideally from a suprapubic aspiration or fresh catheter specimen.

Body surface cultures and gastric aspirates are of limited value in the evaluation of sepsis. Tracheal aspirates may be of value in intubated neonates shortly after birth and immediately after endotracheal tube placement.[8,36,45]

Lumbar puncture

LP to obtain cerebrospinal fluid (CSF) is important in the evaluation of meningitis yet remains controversial. The incidence of meningitis in healthy-appearing infants is low, but the incidence is up to 23% in bacteremic patients. Further, up to 38% of infants with meningitis can have negative blood cultures.[45] A LP should be delayed or cancelled in infants with cardiorespiratory distress, tense or bulging anterior fontanel, severe thrombocytopenia, or infection at the LP site.[36]

Table 20.6 NICE risk factors and clinical indicators of possible infection

	Red flags	Non-red flags
Risk factors	• Parenteral antibiotics given to mother for confirmed or suspected bacterial infection during labor or within 24 hours before or after birth (excluding prophylactic antibiotics) • Suspected or confirmed infection in another baby in the case of a multiparous pregnancy	• Invasive GBS infection in a previous baby • Maternal GBS colonization, bacteriuria, or infection in the current pregnancy • Pre-labor rupture of membranes • Preterm birth following spontaneous labor (<37 weeks gestation) • Suspected or confirmed rupture of membranes for more than 18 hours in a preterm birth
Clinical indicators	• Respiratory distress starting >4 hours after birth • Seizures • Need for mechanical ventilation in a term baby • Signs of shock	• Altered muscle tone, behavior, or responsiveness • Feeding difficulties or intolerance • Abnormal heart rate • Signs of respiratory distress, apnea, or hypoxia • Jaundice within 24 hours of birth • Signs of neonatal encephalopathy • Need for CPR • Need for mechanical ventilation in a preterm baby • Persistent pulmonary hypertension • Temperature abnormality unexplained by environmental factors • Coagulopathy (excessive bleeding, thrombocytopenia, INR > 2) • Oliguria persisting beyond 24 hours after birth • Hypo/hyperglycemia • Metabolic acidosis • Local signs of infection

Note: Red flags are considered strongly suggestive of sepsis.
Abbreviations: CPR = cardiopulmonary resuscitation, INR = international normalized ratio.

CSF parameters in neonates are also controversial. Levels are age-dependent and altered in premature infants. Additionally, if analysis is delayed greater than 2 hours, values may change significantly. Positive findings in CSF include age-adjusted elevated WBC, low glucose concentration, and elevated protein levels.[45]

Radiographs

Chest x-ray may be useful in the evaluation of pneumonia or to evaluate for anatomic causes of respiratory distress. Abdominal x-ray can be used to evaluate intra-abdominal causes of sepsis, such as pneumatosis intestinalis in infants suspected of having necrotizing enterocolitis.

Hematologic evaluation

A WBC count with differential along with neutrophil counts or ratios of immature to total neutrophils (I:T ratio) have relatively poor positive predictive accuracy in the evaluation of neonatal sepsis.[36] Neutropenia may be more specific for neonatal sepsis since only a few other conditions decrease neutrophils in neonates (maternal pregnancy-induced hypertension, asphyxia, and hemolytic disease). However, normal neutrophil counts vary with type of delivery, gestational age, site of sampling, and altitude.[45] I:T ratio has a poor positive predictive value for neonatal sepsis but a very high negative predictive value and can be elevated in up to 50% of uninfected infants.[36,45]

Thrombocytopenia is common in neonatal sepsis but is not sensitive or specific, is often a late indicator of sepsis, and is not useful in evaluating response to therapy.[36,45]

Acute phase reactants and biomarkers

Acute phase reactants and biomarkers can be measured in the evaluation of neonatal sepsis. The most commonly measured acute phase reactants are CRP and procalcitonin. CRP levels typically rise within 6–8 hours of infection and peak at 24 hours. An elevated CRP within 24–48 hours has the best positive predictive value, and two normal CRP values measured at 8–24 hours after birth and again 24 hours later have a negative predictive value of 99.7% for neonatal sepsis.[36,45,46] Procalcitonin is also commonly measured in neonatal sepsis and is more specific and sensitive for infection.[8] It is produced by monocytes and hepatocytes, and levels peak at 12 hours after an infectious episode.[36,45] Procalcitonin is more sensitive and specific for LOS as compared with EOS.[42]

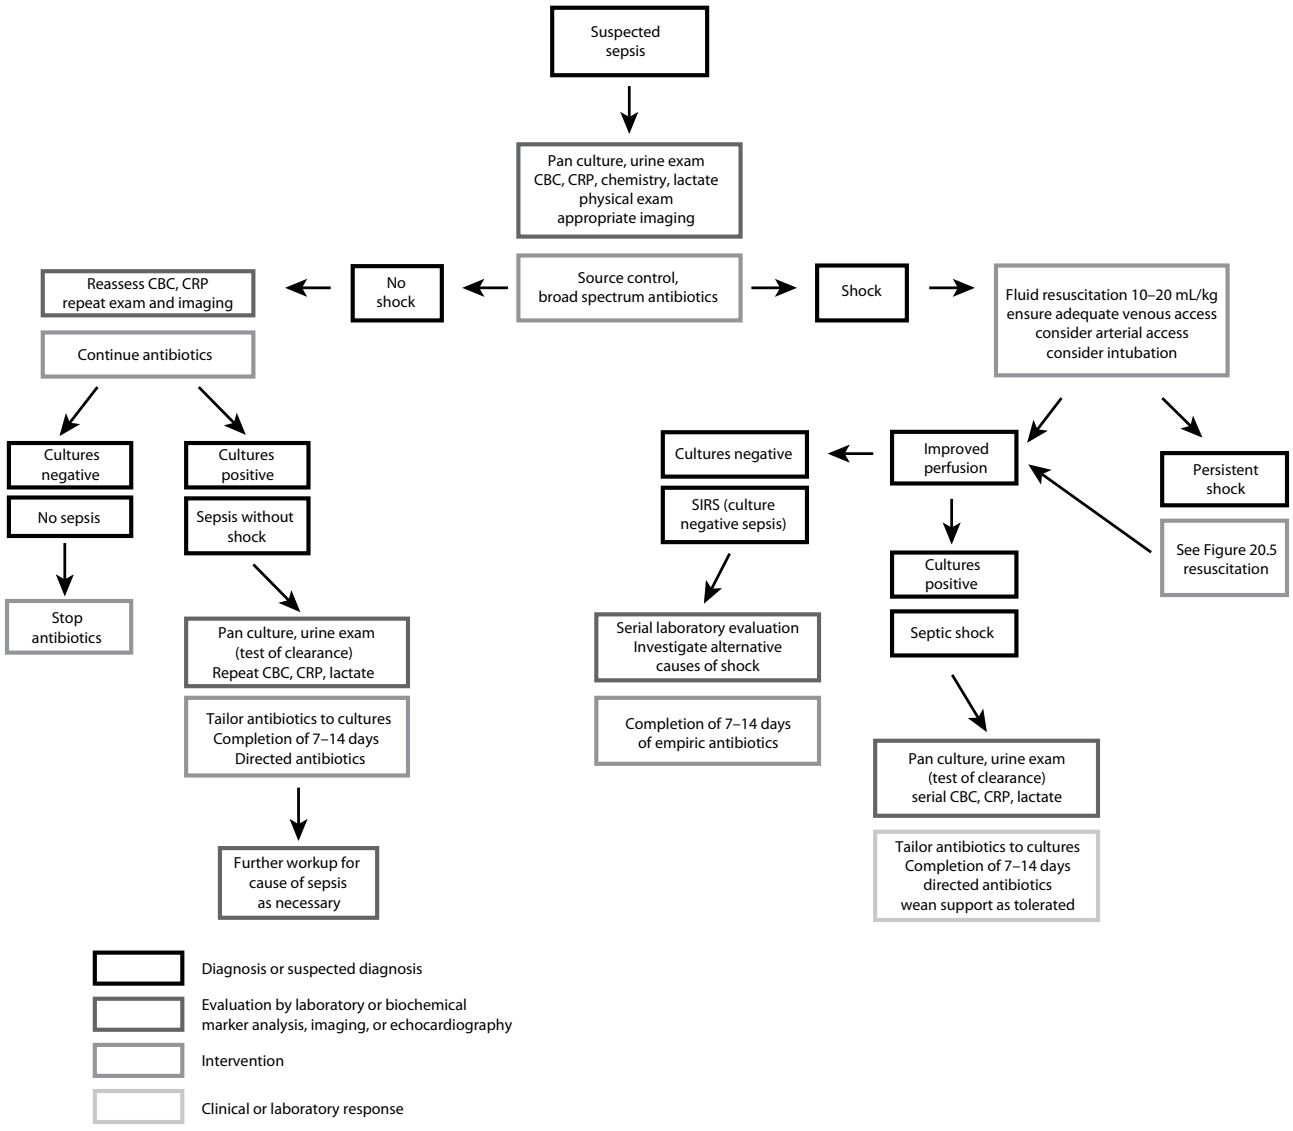

Figure 20.4 Algorithm for management of sepsis.

There is no single biomarker that can be used to reliably diagnose neonatal sepsis. One study evaluated 13 clinical and laboratory signs of sepsis and found that the maximum positive predictive value of any sign studied was 31.3%.[24] Combinations of biomarkers have been evaluated in neonatal sepsis to increase diagnostic accuracy. However, reports on the utility of biomarkers such as CRP, IL-6, serum amylase A, IL-8, procalcitonin, and TNF-α are inconsistent, and no standard biomarker guidelines have been accepted in the screening for neonatal sepsis.[42,47,48]

MANAGEMENT

Prevention strategies

Given the profound morbidity and mortality associated with neonatal sepsis, management should begin with prevention. Significant advances have been made in the prevention of sepsis in both the perinatal and peripartum period as well as in the early postpartum management of neonates. The most significant prevention strategy has been the implementation of prenatal screening and administration of intrapartum antibiotics for GBS infection. The Centers for Disease Control and Prevention published guidelines in 1996 on the prevention of perinatal GBS disease. The 2010 revised guidelines advocate for universal screening for maternal vaginal and rectal GBS at 35–37 weeks gestation and intrapartum antibiotics for women with GBS isolated from urine at any time during the pregnancy, who have a previous infant with invasive GBS disease, or who have tested positive for GBS colonization. Additionally, intrapartum antibiotics are recommended for women whose GBS screening is unavailable at the time of delivery, who deliver at less than 37 weeks gestation, who have a prolonged duration of membrane rupture (>18 hours), who have an intrapartum temperature

(>38°C), or who have a positive nucleic acid amplification test at the time of delivery.[49] Penicillin or ampicillin is recommended for the intrapartum treatment of mothers with GBS. Alternatives for penicillin allergic mothers have not been measured in controlled trials for efficacy but include cefazolin, clindamycin, erythromycin, and vancomycin.[49]

Efforts have also been made in the prevention of LOS sepsis through improved hand hygiene, umbilical cord care, sterile technique during procedures, early breast milk feeding, neonatal skin care, limited use of invasive devices, and uniform practices for insertion, care, and manipulation of essential invasive devices. Although aggressive skin care, including 3% hexachlorophene bathing, can significantly reduce *S. aureus* and other Gram-positive cocci colonization, the significant skin permeability of the neonate leads to absorption and associated neurotoxicity.[50] The World Health Organization recommends dry skin care in developed countries and antiseptic use in developing countries,[51] although many centers routinely apply small amounts of antimicrobials to the umbilicus and circumcision sites. Indeed, a recent randomized controlled trial investigating umbilical cord care demonstrated superiority and safety of chlorhexidine powder to dry care.[52] Additionally, prevention of colonization and infection in nurseries requires adequate space and personnel. Recommendations of space range from 36 to 100 square feet and nurse to patient ratio of 1:4 to1:1, depending on acuity. Although good outcome studies of individual interventions are not possible due to power restrictions, quality assurance and intervention bundle studies indicate that combined implementation of infection control techniques reduces the risk of nosocomial infections. This includes frequent hand hygiene, gowns and gloves, care of invasive devices, sterilization of equipment, and epidemic control techniques.[53,54] Despite the success of these environmental techniques, several well-designed Cochrane reviews failed to produce evidence in favor of prophylactic systemic antibiotics in ventilated newborn infants[55] or neonates with central venous[56] or umbilical catheters.[55] Additional strategies to prevent hospital associated infections include the administration of lactoferrin and probiotic supplementation.[20]

Treatment

Management of neonatal sepsis includes supportive care, source control, and administration of appropriate antibiotics. Significant improvement in the morbidity and mortality of adult and pediatric sepsis has been achieved through goal-directed resuscitation (see Figure 20.5).[57] Unfortunately, the "goal" of resuscitation is not as clear in the neonatal population as it is in adults.[58] At birth, newborns carry a "backpack" of extra salt and water to carry them through the transition to extrauterine life.[59] During this transition and early neonatal life, many hemodynamic parameters such as blood pressure do not have clear "normal" values.[60] In addition, immature cardiovascular and endocrine systems may blunt the appropriate stress response in newborns, making vasopressor, inotrope, calcium, and hormone replacement necessary.[61] Finally, aggressive fluid resuscitation is associated with a significant risk of reopening the ductus arteriosus and potentially worsening perfusion.[62] Nevertheless, fluid resuscitation, vasopressor use, calcium replacement, and endocrine replacement are key components of the therapeutic armamentarium for achieving adequate tissue perfusion.[63,64]

There are no validated clinical signs of shock or poor tissue perfusion without end organ damage. The Surviving Sepsis Campaign guidelines now include pediatric considerations in the management of severe sepsis but do not distinguish between neonates and children. Carcillo et al.[65] provided newborn-specific clinical practice parameters for resuscitation and stabilization of neonates in septic shock (Table 20.7). Resuscitation should include (1) maintaining the airway and attaining adequate oxygenation and ventilation, (2) maintaining circulation defined as normal perfusion and blood pressure, and (3) maintaining threshold heart rates. Therapeutic endpoints include capillary refill of less than 2 seconds, normal pulses with no difference in central and peripheral pulses, warm extremities, urine output of greater than 1 mL/kg/h, normal mental status, normal blood pressure for age, preductal and postductal oxygen saturation difference of less than 5%, and oxygen saturation of >95%.[66] Though frequently assessed for management, studies have demonstrated no association between blood pressure and tissue perfusion,[67] and a weak association among color,[68] capillary refill,[69] and tissue perfusion. Significantly decreased tissue perfusion has several measurable laboratory and biochemical effects in the neonate. In particular, metabolic acidosis, base deficit, and serum lactate can be utilized as markers of poor perfusion.[70] Therefore, improvement in these laboratory markers along with urine output can be used as putative "goals" for resuscitation.

During resuscitation, need for intubation and vascular access should be assessed. Fluid boluses of 10 mL/kg should be given up to 60 mL/kg in the first hour to attain normal perfusion and blood pressure. Vasoactive support may be required, but pulmonary vascular resistance should be considered when selecting a vasopressor and support for persistent pulmonary hypertension of the newborn should be initiated if needed.[66] The most commonly studied and prescribed adrenergic medications include dopamine, dobutamine, and epinephrine. In addition, milrinone is a frequently used phosphodiesterase inhibitor. Due to the differing proportions of alpha- and beta-adrenergic receptors in the neonate, there has been significant skepticism regarding the utility of alpha-specific medications such as phenylephrine or norepinephrine, although they are used routinely in older patients. Nevertheless, a prospective trial evaluating norepinephrine demonstrated improved tissue perfusion and relative safety in the neonate with shock refractory to fluid and classic vasopressors.[71] Similarly, several reports of neonatal use of vasopressin agonists in refractory shock and post cardiopulmonary bypass stun

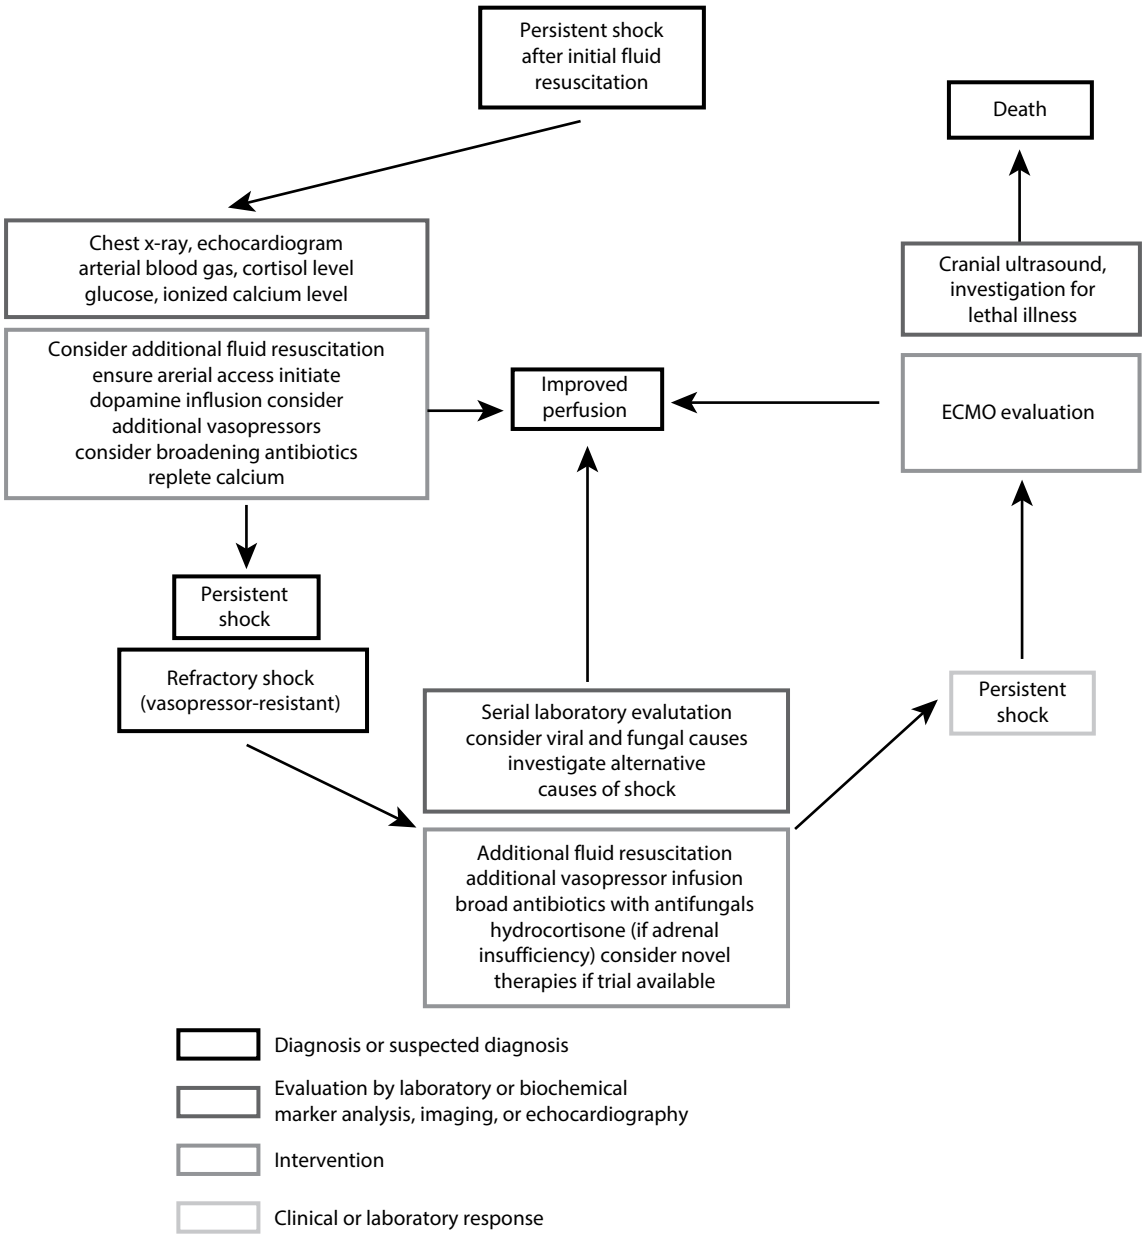

Figure 20.5 Algorithm for management of shock.

suggest that vasopressin[72] and terlipressin[73] appear to be effective and relatively safe. Nonetheless, current neonatal guidelines generally favor dopamine over dobutamine as an initial choice of vasopressor, and epinephrine as a rescue medication for dopamine-refractory shock, despite ongoing debate about the optimal pressor for different types of shock.[61] Because neonatal sarcomeres are immature, sarcoplasmic calcium stores are significantly less[74]; this results in a profound dependence on serum calcium for successful contractility of the myocardium and tone of the arteriolar vascular tree. Calcium chloride infusions, along with various other forms of calcium replacement, have been strongly advocated in the pediatric and anesthesia communities,[75] but safety and intravenous access issues have not been studied in the setting of calcium infusion for septic shock. Nevertheless, most units prefer to add calcium to intravenous fluid and parenteral nutrition, as well as intravenous calcium boluses to maintain calcium in the normal range.

Evidence supports endocrine replacement therapy in the setting of neonatal shock refractory to vasopressor treatment.[76] Although there is inadequate evidence to support empiric corticosteroid use,[77,78] measurement of serum cortisol concentrations and absolute and relative adrenal insufficiency can identify neonates who will benefit from hydrocortisone replacement therapy.[79] Corticosteroids have two main classes of effects: genomic and nongenomic. Late effects, such as alterations in IL-2 production and secretion, are due to changes in leukocyte gene regulation. Early nongenomic effects, on the other hand, are responsible for the efficacy of endocrine

Table 20.7 Neonatal sepsis goals and therapeutic endpoints for resuscitation and stabilization

	Goals	Therapeutic endpoints
Initial resuscitation (first hour)	• Maintain airway • Maintain circulation • Maintain threshold heart rate	• Capillary refill ≤2 seconds • Normal pulses • No difference between peripheral and central pulses • Warm extremities • UOP >1 mL/kg/hour • Normal mental status • <5% difference in preductal and postductal oxygen saturation • Oxygen saturation of >95%
Stabilization	• Maintain threshold heart rate • Maintain perfusion and blood pressure • $ScvO_2$ >70% • CI >3.3 L/min/m^2 • SVC flow >40 mL/kg/min	• Maintain endpoints for initial resuscitation • Absence of right to left shunting, tricuspid regurgitation, or right ventricular failure • Normal glucose and calcium levels • Normal INR • Normal anion gap and lactate • Fluid overload <10%

Source: Adapted from Carcillo et al., *J. Pediatr. (Rio J)*, 78(6), 449–66, 2002.
Abbreviations: UOP = urine output, $ScvO_2$ = central venous oxygen saturation, CI = cardiac index, SVC = superior vena cava, INR = international normalized ratio.

replacement in shock. In particular, corticosteroids lead, in a nongenomic, rapid fashion, to the prevention of endocytosis of adrenergic receptors and downregulation of secondary messenger systems that lead to tachyphylaxis to both autologous and extrinsically infused adrenergic vasopressors.[76] Successful response to hydrocortisone therapy generally is immediate (minutes to hours)[80] and requires replacement of stress dose cortisol levels only, or hydrocortisone 1 mg/kg every 6 hours. There are currently no evidence-based guidelines on weaning hydrocortisone in neonates.[81]

Therapeutic endpoints for neonatal stabilization beyond the first hour include maintaining the initial resuscitation targets and maintaining a central venous oxygen saturation ($ScvO_2$) of greater than 70%, normal glucose and ionized calcium levels, superior vena cava flow greater than 40 mL/kg/min, cardiac index greater than 3.3 L/min/m^2, normal INR, normal anion gap, normal lactate, fluid overload of less than 10%, and absence of right to left shunt, tricuspid regurgitation, or right ventricular failure. In the case of refractory shock, pericardial effusion, pneumothorax, blood loss, hypoadrenalism, hypothyroidism, inborn errors of metabolism, or heart disease should be evaluated and treated as discussed above. If these causes are excluded, practitioners should consider extracorporeal membrane oxygenation (ECMO).[65,66]

Source control is essential in the treatment of neonatal sepsis. EOS is most commonly caused by an ascending or transplacental transmission of infection, while LOS is most commonly related to indwelling catheters, ventilator-associated pneumonia, or urinary tract infections. For EOS, source control consists of clamping and cutting the umbilical cord. For LOS, source control should include removal of catheters and extubation as early as clinically possible. Patients should also be evaluated for other causes of infection, and aggressive source control should be initiated for infected or necrotic tissue.

Selection of initial antibiotic therapy can be difficult. Blood cultures should be obtained, and empiric antibiotics should be administered within 1 hour of the identification of sepsis.[6] The epidemiology of EOS continues to change rapidly, and while a penicillin and aminoglycoside appear to be optimal peripartum therapy, integration of individual unit antibiograms and ongoing surveillance are necessary for treating LOS. Furthermore, decreasing Gram-negative and Gram-positive sepsis has led to a commensurate rise in anaerobic, fungal, and viral sepsis. There is inadequate evidence from randomized trials to support any particular antibiotic regimen in the initial treatment of suspected LOS in the newborn.[82] Although variations on penicillins (such as antipseudomonal penicillins or beta-lactamase inhibitors) and low cross resistance between aminoglycosides help individual units develop broad spectrum strategies, increasing rates of methicillin-resistant *Staphylococcus aureus* (MRSA) and multidrug resistant Gram-negative infections make optimal broad spectrum coverage a moving target. Increasingly, initial therapy includes vancomycin in units highly colonized with MRSA as well as an antifungal agent due to the increased incidence of *Candida* spp. sepsis as well.[83] Indeed, there are randomized controlled trials that support prophylactic,[84] initial, and completion antifungal therapy.[85,86]

Once culture-proven sepsis is documented, it is safe and appropriate to narrow the spectrum of initial antibiotic therapy toward the pathogen identified. The treatment duration varies from 10 to 14 days depending on the pathogen, while treatment for meningitis is usually longer. Duration should be adjusted based on response to therapy or complications including abscesses, osteomyelitis, or endocarditis.[36] For infants with neonatal sepsis and negative blood cultures, antibiotic duration should be determined by the clinical course and the risk of prolonged antibiotic therapy.[45] Monitoring response to antibiotic therapy should be performed with repeat blood cultures and laboratory values to document bacterial clearance. Trends in inflammatory biomarkers have been evaluated to determine response to antibiotic therapy and may allow for the early discontinuation of antibiotics in healthy appearing neonates.[42] However, further investigations are needed on targeted antibiotics and biomarkers to guide duration of therapy.

New therapies and preventive strategies

Several new therapies have been proposed for the management of neonatal sepsis. Intravenous immunoglobulin (IVIG) was evaluated due to its potential to supplement the immune system by augmenting antibody-dependent cytotoxicity and improving neutrophil function. An international study group of 113 hospitals and a Cochrane review of 10 controlled trials found no effect on morbidity or mortality with IVIG administration.[20] Recombinant granulocyte colony-stimulating factor was also evaluated in neonatal sepsis and was found to have no effect on severity of illness, morbidity, or mortality.[36,87] Pentoxifylline, an agent that improves microcirculation and decreases TNF-α, was studied in culture positive neonatal sepsis and may have potential for improved survival.[20,88] However, this response needs to be evaluated in a large multicenter trial.

MULTIDRUG RESISTANCE AND OPPORTUNISTIC INFECTIONS

Intrapartum antibiotic prophylaxis for maternal GBS has significantly decreased vertical transmission and the incidence of EOS due to GBS.[89] However, the use of prophylactic and broad spectrum antibiotics has caused a shift in the causative organisms and has increased the proportion of non-GBS organisms. *E. coli* has emerged as a leading non-GBS cause of EOS.[23] Gram-negative sepsis is linked to increased severity of disease and death in newborns, and raises significant concerns about the effect of widespread antibiotic use for prophylaxis and optimal prevention and treatment approaches.[34,89]

Previous studies have shown rapid development of and increased rates of resistance with the use of cefotaxime for the routine treatment of EOS.[45,90] Therefore, cefotaxime use should be restricted for infants with meningitis caused by Gram-negative bacteria.[91]

Candida species are the most common fungal infectious agents encountered in the NICU. *Candida* infections account for 1%–4% of all NICU admissions and approximately 10% of nosocomial sepsis in VLBW neonates.[92–94] However, colonization by *Candida* does not necessarily lead to invasive infection. A retrospective review by Manzoni et al.[95] found that colonization occurred in 32% of VLBW neonates at a single institution. The median age for the invasive fungal infections in this study was 21 days. The Neonatal Research Network prospectively collected data on neonates weighing <1000 g to study risk factors, causes, and outcomes of extremely low birth weight (ELBW) neonates with candidiasis in the NICU.[93] They found that invasive candidiasis was documented in 7% of ELBW neonates, with 68% survival. *C. albicans* and *C. parapsilosis* were the most commonly identified species with similar rates and mortality in blood infections and meningitis, with *C. albicans* having an increased mortality rate at 42% versus 20% overall. Furthermore, neonates with birth weight between 401 and 750 g and the use of a third-generation cephalosporin were found to increase the risk of developing candidiasis, while enteral feeding appeared protective.[93] Other factors associated with invasive fungal infections in colonized patients were: colonization of central venous catheter, colonization in multiple sites, low birth weight, prematurity, days on supplemental oxygen, positive gastric culture, positive endotracheal culture, intubation, and presence of bacterial sepsis.[95]

VIRAL SEPSIS

Neonatal viruses have been increasingly identified in infants evaluated for bacterial sepsis despite the lack of clinical indicators.[96,97] The VIRIoN-I study prospectively evaluated the incidence of respiratory viral infections and found that 6% of NICU sepsis evaluations had a viral infection detected.[96] Infants diagnosed with a respiratory virus had a longer hospital stay and were more commonly diagnosed with bronchopulmonary dysplasia (BPD).[97] Neonatal viral infections include coronavirus, enterovirus, human metapneumovirus, influenza, parainfluenza virus, respiratory syncytial virus, rhinovirus, herpes simplex virus, coxsackievirus, echovirus, cytomegalovirus, human immunodeficiency virus, varicella-zoster, rubella virus, influenza, and parechovirus.[28,36] Antivirals such as acyclovir, ganciclovir, and oseltamivir can be used in the treatment of infected neonates and have improved the morbidity and mortality associated with viral infection.[28,36]

OUTCOMES

Neonatal sepsis and its associated mortality is declining.[1] However, survival can be associated with adverse long-term outcomes. These include cerebral palsy, visual impairment, delayed psychomotor development, low Bayley Scales of Infant Development scores, overall poor neurodevelopment, and impaired growth.[2,20] Recurrent postnatal infection was found to be a risk factor for progressive white matter injury

in premature infants, which may be related to the adverse neurodevelopmental sequelae observed after neonatal sepsis.[98] Preterm infants exposed to chorioamnionitis and subsequent EOS have an increased incidence of BPD resulting in chronic lung disease and poor developmental outcomes. Sepsis-induced endocarditis and thrombosis can cause rare complications such as pulmonary embolism, valvular damage, and infectious thromboembolism.[36]

CONCLUSIONS

Neonatal sepsis continues to be a major cause of long-term morbidity and mortality. As the prevention, identification, and therapy of sepsis advance, the epidemiology and bacteriology of the disease shift making optimal treatment of sepsis an evolving process.[6] Continued evaluation of current management guidelines and the development of preventive, diagnostic, and therapeutic measures for neonatal sepsis are essential.

Hematological problems in the neonate

ANDREA M. MALONE AND OWEN P. SMITH

INTRODUCTION

Hematopoiesis in the fetus and neonate is in a constant state of flux and evolution as the newborn adapts to a new physiological milieu. Hematological problems may present during this period as a result of a genetic defect, immaturity, or stress, and present a major diagnostic and therapeutic challenge to the neonatologist and hematologist alike. Advances in molecular techniques have allowed the elucidation of the cellular mechanisms that give rise to some of these disorders of the hematopoietic system. It is hoped that this chapter will give the reader a broad understanding of the major hematological disorders seen in the neonatal period, especially those involving platelets, white cells, red cells, and clotting proteins.

PLATELETS

The normal range of the platelet count is similar in fetal life to that seen in adulthood, being in the range of 150×10^9/L to 400×10^9/L. Thrombocytopenia, defined as a blood platelet count of below 150×10^9/L, is the most common hematological abnormality encountered in the neonatal period, with a reported frequency approximating 0.1%–0.2% in unselected newborns and up to 35% in infants in intensive care units.[1–3] Platelet counts increase with advancing postnatal age, with thrombocytopenia present in about 30% of small for gestational age infants.[4] Severe thrombocytopenia (platelet count less than 50×10^9/L) is uncommon in the healthy newborn population, but has an incidence in neonates admitted to the neonatal intensive care unit of between 2.4 and 5%.[5] The differential diagnosis of thrombocytopenia in the neonatal period is similar to thrombocytopenia in older children with a number of additions that include inherited disorders, and those that arise due to pathophysiological events unique to the antenatal and perinatal periods. Although most automated counters in the laboratory are designed to detect platelet clumps, it is essential to confirm that the low platelet count is genuine by visual inspection of the blood smear before initiating further investigations. Pseudo thrombocytopenia due to platelet clumping is not associated with bleeding and does not require treatment. The approach to the investigation of thrombocytopenia should be tailored to the individual infant and mother. Assessment of the baby's general condition is very important as healthy neonates with thrombocytopenia usually have an immune or an inherited etiology, whereas the presence of hepatosplenomegaly, mass lesions, hemangiomas, and congenital anomalies will point toward a totally different spectrum of causes. A detailed maternal history should always be obtained, with specific focus on bleeding problems, hypertension, and drug ingestion, and also with respect to viral infections or connective tissue diseases. The causes of thrombocytopenia are divided into two broad categories: those due to increased platelet destruction and those due to decreased platelet production. Occasionally, both mechanisms contribute to the thrombocytopenia.

Increased destruction

Increased destruction of platelets is seen in a number of neonatal conditions. It encompasses immune-mediated platelet destruction or consumption.

AUTOIMMUNE THROMBOCYTOPENIA

This is seen in term babies that are generally clinically well and is mediated by the passive transfer of maternal autoantibodies in mothers with autoimmune disorders such as immune thrombocytopenic purpura (ITP), systemic lupus erythematosis, and hypothyroidism.[6] Thrombocytopenia is seen in about 10% of the infants born to mothers with ITP. The diagnosis is usually apparent from the mother's medical history. The risk of significant morbidity and mortality is minimal as the infant platelet count is rarely $<50 \times 10^9$/L. The nadir typically occurs between 2 and 5 days of age; therefore, affected infants need to be carefully monitored. The most feared complication of neonatal thrombocytopenia is intracranial hemorrhage; however, this very rarely happens

in autoimmune thrombocytopenia[7] and is generally not related to the mode of delivery of the infant.[8] Symptomatic infants can be effectively treated with intravenous immunoglobulin (IVIG). Platelet transfusion should be restricted to treat hemorrhage or severe thrombocytopenia.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Neonatal alloimmune thrombocytopenia (NAIT) is characterized by marked thrombocytopenia in the fetus and neonate. It occurs following maternal sensitization to a paternally inherited fetal platelet antigen that is lacking in the mother. The mother forms an IgG antibody that crosses the placenta and destroys fetal platelets. In contrast to hemolytic disease of the newborn (the red blood cell analog of NAIT), NAIT may occur during the first pregnancy. It complicates between 1 in 100 and 1 in 2000 births.[9] NAIT typically presents as an isolated severe thrombocytopenia in an otherwise healthy child at birth. The most serious complication is intracranial hemorrhage, which occurs in 10%–20% of affected newborns.[10] The risk of severe thrombocytopenia and intracranial hemorrhage is greater in alloimmune than in autoimmune thrombocytopenia. For testing to confirm NAIT, it must reveal both a platelet antigen incompatibility between the parents and a maternal antibody derived against that antigen. The most commonly involved antigen is HPA-1a. The mainstay of treatment is transfusion of donor-matched, antigen negative platelets with neonatal specification, and IVIG. Initial evaluation should include a cranial ultrasound to detect hemorrhage. The thrombocytopenia typically resolves over 3–6 weeks. NAIT is very likely to recur in subsequent pregnancies, and the thrombocytopenia is often more severe in the next child.

Peripheral consumption

Increased destruction of platelets leading to thrombocytopenia may also occur from increased peripheral consumption of platelets.

HYPERSPLENISM

This is an uncommon cause of thrombocytopenia in the neonate due to splenic sequestration of platelets. It can be associated with an enlarged spleen. Underlying disorders include hemolytic anemia, congenital viral infection, congenital hepatitis, and portal vein thrombosis. Management is directed at the underlying cause, and platelet transfusions are used supportively.

KASABACH–MERRITT PHENOMENON

Kasabach–Merritt syndrome (KMS) is the association of a giant cavernous hemangioma and disseminated intravascular coagulation. Thrombocytopenia results from shortened platelet survival caused by the sequestration of platelets in the vascular formation. The vascular tumors associated with the KMS are usually kaposiform hemangioendotheliomas (KHE) and not the more usual infantile hemangiomas that are seen in early childhood. The KHE lesions have a predilection for the trunk, retroperitoneum, and proximal extremities, and less frequently the cervicofacial region. Like other tumors, a KHE is dependent on the formation of new blood vessels from preexisting vasculature (angiogenesis), and this process is regulated by several proangiogenic and anti-angiogenic molecules. Because of their large size and infiltrative nature, complications such as hemorrhage, airway obstruction, and congestive cardiac failure are not uncommon in a small subset of these patients. The consumptive coagulopathy, which is seen in approximately 25% of cases, is usually low grade and compensated. Fortunately, spontaneous regression of the tumor occurs in the majority of cases.

Over the past three decades, medical treatment for these potentially life-threatening lesions has included the use of corticosteroids alone or in combination with vincristine and/or interferon-alpha, together with the judicious use of blood products and clotting factor concentrates. More recently, because of their role in tumor growth, there has been a move to target the platelet by using antiplatelet agents and withholding platelet infusions even in those patients who have significant thrombocytopenia and are coagulopathic. Excellent response rates have been achieved using antiplatelet therapy with vincristine.[11]

THROMBOSIS

Thrombocytopenia can be caused by hypercoagulability and associated consumption of platelets. A low platelet count may be the presenting sign of arterial or venous thrombosis in the neonate.

TYPE 2B VON WILLEBRAND DISEASE

In this type of von Willebrand disease (vWD), the structurally abnormal von Willebrand factor (vWF) has increased affinity for the glycoprotein 1b receptor on the platelet surface. This may lead to platelet aggregation and thrombocytopenia.[12]

Decreased production

Neonatal thrombocytopenia due to decreased platelet production encompasses the inherited disorders and diseases associated with bone marrow infiltration or suppression.

INHERITED BONE MARROW FAILURE SYNDROMES

The inherited bone marrow failure syndromes (IBMFSs) are a rare yet clinically important cause of neonatal hematological manifestations. It is of vital importance to identify them as many of these syndromes confer risks of multiple medical complications, including an increased risk of cancer. Some IBMFSs may present with cytopenias in the neonatal period, whereas others may present only with congenital physical anomalies and progress to pancytopenia later in life.

Thrombocytopenia with absent radii (TAR) is a rare, autosomal recessive disorder that is usually diagnosed at birth as the vast majority of these patients are thrombocytopenic and have the pathognomonic physical sign of bilateral absent radii. Other skeletal abnormalities involving the ulnae, fingers, and lower limbs are less commonly seen.

TAR differs from Fanconi anemia (FA) in several ways: the absent radii are accompanied by the presence of thumbs, the thrombocytopenia is the only cytopenia, and evolution to aplastic anemia and leukemia is rare.[13] The majority of children with TAR have severe thrombocytopenia and recurrent significant bleeding episodes in the first 6 months of life. The genetics of TAR were unknown until recently; however, next-generation sequencing has revealed that TAR patients inherit a deletion of chromosome band 1q21.1 from one parent and a single nucleotide variant in the RBM8A gene from the other parent, thus following an autosomal pattern of inheritance. The mainstay of treatment is judicious transfusion of single donor platelet concentrates as required for thrombocytopenia and orthopedic intervention for functional optimization of the upper limbs. The thrombocytopenia tends to improve over time.[14]

Congenital amegakaryocytic thrombocytopenia (CAMT) is an extremely rare autosomal recessively inherited disorder of infancy and early childhood. Of all the IBMFS, it is the one most likely to present in the neonatal period. Affected newborns show no physical abnormalities. The thrombocytopenia is non-immune and usually severe, and pancytopenia can ensue. The condition results from a mutation in the c-MPL gene that encodes the thrombopoietin (TPO) receptor. Management is largely symptomatic with platelet transfusions and antifibrinolytics for patients with bleeding. Currently, the only curative option for CAMT is hematopoietic stem cell transplantation (HSCT).[14]

FANCONI ANEMIA

FA is a chromosomal instability disorder caused by genetic defects in DNA repair. Bone marrow failure is rarely present in infancy. It is characterized by physical abnormalities (commonly short stature, skin hyper- or hypopigmentation, upper limb and thumb abnormalities), bone marrow failure, and an increased risk of malignancy. Progressive bone marrow failure with pancytopenia typically presents in the first decade. Thrombocytopenia is usually the first cytopenia to appear but rarely in the neonatal period. The diagnosis of FA rests upon the detection of increased chromosomal breakage in lymphocytes after exposure to DNA cross-linking agents such as di-epoxybutane or mitomycin C. Recent advances in genomic technology, including next-generation sequencing and whole exome analysis, have accelerated gene discovery efforts. Whereas the first genetic mutation causing FA was discovered more than 20 years ago, there are currently 16 known genes that cause FA. Abnormalities of FA genes are inherited in an autosomal recessive manner except for pathogenic variants in *FANCB*, which are inherited in an X-linked manner.[15] A multidisciplinary team approach is required in the management of infants with FA. HSCT is the only curative treatment for the hematological manifestations of FA.

INHERITED PLATELET DISORDERS

The inherited thrombocytopenias comprise a group of disorders in which platelet numbers are reduced. In the vast majority of patients, the platelet count is only mild to moderately reduced, and therefore, significant spontaneous hemorrhage tends not to be problematic. Spontaneous bleeding is, however, a prominent clinical feature of Bernard–Soulier syndrome (BSS) and Wiskott–Aldrich syndrome (WAS). Immune-mediated thrombocytopenia is a major differential diagnosis in children with low platelet counts, and therefore, making the correct diagnosis of these conditions will prevent the useless and potentially dangerous prescribing of immunosuppressants such as corticosteroids.[12]

BERNARD–SOULIER SYNDROME

This is an autosomal recessive disorder of platelet function and number. It presents with moderate to severe thrombocytopenia, circulating "giant" platelets on the blood smear, and bleeding. On laboratory testing, platelets fail to aggregate with ristocetin. The underlying molecular defect results in an absent or nonfunctioning platelet membrane receptor for vWF. In the affected infant with BSS, platelets should be transfused if there is bleeding, or if the thrombocytopenia is severe in order to prevent spontaneous hemorrhage.[16]

PSEUDO-vWD

This is an autosomal dominant disorder characterized by mild intermittent thrombocytopenia, mild bleeding, absence of high molecular weight vWF multimers, and increased ristocetin-induced platelet aggregation. It can be differentiated from type 2B vWD, where the mutation resides in the vWF protein by spontaneous aggregation of the patients' platelets with normal plasma.[12]

TYPE 2B vWD

In this type of vWD, the structurally abnormal vWF has increased affinity for the glycoprotein 1b receptor on the platelet surface. This may lead to platelet aggregation and thrombocytopenia. It is clinically and biochemically very similar to pseudo-vWD. Type 2B is diagnosed by demonstrating enhanced platelet agglutination induced by low concentrations of ristocetin.[12]

Montreal platelet syndrome

This syndrome is characterized by thrombocytopenia, large platelets, spontaneous platelet aggregation, and a reduced response to thrombin-induced aggregation. It can be distinguished from BSS by its autosomal dominant inheritance and normal platelet response to ristocetin.[12]

Gray platelet syndrome

An extremely rare mild bleeding disorder for which both autosomal dominant and recessive inheritance have been described, gray platelet syndrome is characterized by the platelet's inability to store alpha granule proteins.[17] Thrombocytopenia is mild, platelets are large, and the absence of alpha granule content gives the platelets a gray appearance on blood smears.

Paris–Trousseau syndrome

This is an autosomal dominant syndrome composed of mild thrombocytopenia, a mild bleeding tendency, giant alpha-granules in a subpopulation of platelets, bone marrow micromegakaryocytes, and a deletion of the long arm of chromosome 11q that includes the FLI1 gene that is essential for megakaryocyte production.[18] There are several other congenital anomalies, including mental retardation, cardiac anomalies, and craniofacial abnormalities.

Wiskott–Aldrich syndrome

The WAS is inherited as an X-linked recessive trait and is characterized by moderate to severe thrombocytopenia, eczema, and a predisposition to infection. Platelets in WAS are typically small. It is often fatal in the early teens due to infection, lymphoreticular malignancy, or bleeding. Hemorrhagic events in this syndrome are common during the first 2 years of life.[12]

WAS VARIANTS (X-LINKED THROMBOCYTOPENIA)

This is a heterogeneous group of thrombocytopenic disorders with X-linked inheritance. The thrombocytopenia is usually less severe in WAS variants and requires no treatment.

Oculocutaneous Albinism—Hermansky–Pudlak and Chediak–Higashi syndromes

Oculocutaneous albinism denotes a group of inherited disorders characterized by reduced or absent pigmentation of the skin, hair, and eyes. While the majority of these patients have an isolated platelet storage pool defect, in some, accompanying low platelet counts can occur.

The Hermansky–Pudlak syndrome is an autosomal recessive disorder with oculocutaneous albinism and a platelet dense-granule defect. The bleeding tendency is usually mild and is related to a platelet function defect and not thrombocytopenia.

Like the Hermansky–Pudlak syndrome, the Chediak–Higashi syndrome is also an autosomal recessive condition with a platelet dense-granule defect and associated partial oculocutaneous albinism. Features of the syndrome may also include neutropenia and peripheral neuropathy. Thrombocytopenia usually occurs during the accelerated phase of the disease, which involves the development of pancytopenia, hepatosplenomegaly, lymphadenopathy, and extensive tissue infiltration with lymphoid cells.[12]

MYH9-related thrombocytopenia syndromes

May–Hegglin anomaly (MHA), Fechtner syndrome, Sebastian platelet syndrome, and Epstein syndrome constitute a group of related disorders with autosomal dominant inheritance and giant platelets.[19] Thrombocytopenia is mild; bleeding is infrequent and rarely life-threatening. Döhle-like inclusions within granulocytic cells are often seen on the blood smear. These disorders can also be associated with sensorineural deafness, glomerulonephritis, and cataracts. Platelet function has been reported to be normal in some and impaired in others.

CONGENITAL INFECTIONS

Thrombocytopenia may occur with congenitally acquired viral infections, including rubella, herpes virus, enterovirus, human immunodeficiency virus, and cytomegalovirus. They rarely produce severe thrombocytopenia, and therefore, therapeutic intervention in the form of platelet transfusion is only indicated when there is severe thrombocytopenia or active bleeding, or surgical intervention is being considered.[20]

NEONATAL INFECTIONS

Late onset thrombocytopenia is most often caused by neonatally acquired infections. Sepsis due to gram-negative bacteria results in particularly severe thrombocytopenia.

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is a common and serious gastrointestinal disorder that predominantly affects premature infants. Ninety percent of neonates with NEC develop late onset thrombocytopenia. It is often severe and associated with bleeding.[21]

MISCELLANEOUS CONDITIONS

Other associations of neonatal thrombocytopenia include birth asphyxia; maternal pregnancy-induced hypertension; maternal drug use; disseminated intravascular coagulation; primary microangiopathic hemolytic anemia, including hemolytic uremic syndrome; transient abnormal myelopoiesis associated with Down's syndrome (discussed later); trisomies 21, 18, and 13; hemophagocytic lymphohistiocytosis (HLH; discussed in the section on coagulation); osteopetrosis; bone marrow infiltration with congenital leukemia or neuroblastoma; and inborn errors of metabolism.

DEVELOPMENTAL HEMOSTASIS

Neonates and infants have a rapidly developing hemostatic system, with developmental changes occurring over months, weeks, or even days.[22] Plasma levels of many of the hemostatic coagulation factors are lower in newborns than in older children and adults.[23] Both full-term and preterm neonates are born with low levels of most procoagulant factors, including all of the contact activation factors (XII, XI, prekallikrein, and high molecular weight kininogen) and vitamin K-dependent factors (II, VII, IX, X). In preterm infants, these levels are even lower. The natural anticoagulants, antithrombin, protein S, and protein C are also low at birth. The plasma levels of the procoagulant cofactors, factor V and factor VIII, and fibrinogen are the same in term infants as in adults. Like the coagulation system, the fibrinolytic system, of which plasminogen is the major protein, is also physiologically immature in the neonate.[24] Elevated

levels of tissue plasminogen activator and plasminogen activator inhibitor also reflect the reduced fibrinolytic activity in neonates.

Despite the deficiencies of multiple hemostatic factors, healthy neonates have normal hemostasis. Although often characterized as "immature," the neonatal hemostatic system is functionally balanced with no tendency toward coagulopathy or thrombosis.

Inherited bleeding disorders

Deficiencies of factor VIII and IX are known as hemophilia A and B, respectively. The incidence is 1:5000 male births (FVIII) and 1 in 20,000 males (FIX). They are inherited in an X-linked manner; thus, females are carriers of the defect, and males with the abnormal gene express the disease. Persons with hemophilia are classified based on their plasma factor activity [severe (<1%), moderate (<5%), or mild (>5%)]. When there is a family history of hemophilia, newborns are usually diagnosed early with cord blood sampling as the condition is anticipated. Making the diagnosis of severe or moderate hemophilia A in the neonate is usually straightforward. However, making the diagnosis of mild hemophilia can be challenging due to increased FVIII activity resulting from the stress of delivery. Levels should be repeated at 6–12 months of age if mild FVIII deficiency is expected. However, 30% of all individuals with hemophilia A and B arise from *de novo* mutations, and it may be some time before a firm diagnosis is made as a significant number of these children may be seen in the general pediatric setting. Hemophilia A and B are clinically indistinguishable. In the severe form, the phenotype is characterized by bleeding into the joints and soft tissues. In the neonate, bleeding may present as a postprocedural bleed or an intracranial hemorrhage. Both the factor VIII and factor IX genes were sequenced and cloned over 20 years ago, and as a result, recombinant factor concentrates are now the treatment of choice in these conditions.[25]

Hemorrhagic complications in moderate and severe hemophilia A and B may become obvious after birth especially if the child is circumcised. The incidence of intracranial hemorrhage in neonates with severe hemophilia is estimated to be between 1% and 4%.[26,27] The severity and type of bleeding are related to the absolute level of circulating plasma VIII:C. A minimal effective level for hemostasis is about 25%–30% for hemophilia A and 20%–25% for hemophilia B. Those with severe deficiency (less than 1%) usually experience repeated and often spontaneous hemorrhages. While muscular bleeding is by far the commonest clinical event, other spontaneous hemorrhagic manifestations frequently occur and may be life-threatening. Successful treatment in acute or potentially acute (pre-surgery) bleeding is usually achieved with adequate and prompt factor replacement therapy. The level of factor concentrate required to achieve adequate hemostasis will depend on the type of bleeding.[28]

VON WILLEBRAND DISEASE

vWD is the most frequently inherited bleeding disorder, affecting approximately 1% of the population, and is transmitted in autosomal dominant or recessive patterns. Bleeding tends to be predominantly mucocutaneous. There are three main categories of vWD based on the quantitative level or function of vWF: type 1, 2, or 3. Type 2 is further divided into four separate subtypes: 2A, 2B, 2M, and 2N. There is significant phenotypic heterogeneity even among members of the same family. The majority of individuals have type 1 vWD with type 3 vWD being the rarest form of the disease and having the most severe bleeding phenotype due to complete or almost complete deficiency of vWF. Typically, only patients with type 3 or some type 2 vWD present with bleeding as neonates.[29] Bleeding can occur after surgery or trauma. Bleeding into joints is rare and typically only seen in individuals with severe type 3 disease. The diagnosis of vWD is based on three main laboratory assays: (i) quantitative measurement of vWF in plasma, (ii) activity of vWF and its ability to bind platelets, (iii) FVIII activity. High molecular weight multimer analysis can be performed to help differentiate type 2 varieties.[25]

The management of bleeding in a neonate with vWD is typically with plasma-derived FVIII products that contain vWF. Desmopressin can be used to stimulate endogenous vWF release; however, there is a significant risk of hyponatremia and consequent seizures, especially in very young children.[28] Its use in neonates is not recommended.

OTHER COAGULATION FACTOR DEFICIENCIES

Deficiencies of all coagulation factors have been described. However, it should be remembered that the number of patients with hemophilia A greatly outnumbers all of these put together. Common features of these rarer forms of coagulation factor deficiencies are variable bleeding tendencies and autosomal recessive inheritance.[25,28]

Acquired bleeding disorders

The acquired coagulation disorders are far more common than the inherited disorders and are usually associated with multiple coagulation factor deficiencies.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

HLH is a rare syndrome of infancy and childhood that manifests as a hyperinflammatory state resulting from pathologic immune activation. HLH can present as both a familial disorder and as an acquired one, in association with infection, malignancies, or rheumatologic disorders. The classical clinical features include fever, splenomegaly, cytopenias, hypertriglyceridemia, hypofibrinogenemia, hyperferritinemia, lymphadenopathy, skin rash, jaundice, and edema.Elevation of ferritin > 10,000 g/dL has been shown to be highly sensitive and specific for HLH.[30] Although it

can occur in all age groups, neonatal-onset HLH is rare. Identified genetic defects are present in 45% of patients that present with HLH less than 1 month of age.[31] Therefore, mutational analyses for UNC13D and perforin gene (PRF1) should be performed in neonates suspected of having HLH. Early recognition and treatment is necessary to prevent disease progression. Remission can be achieved with the use of etoposide-based chemotherapy regimens in conjunction with immune modulating medications such as ciclosporin and corticosteroids. The only definitive cure, however, for patients with familial HLH is HSCT.[31]

VITAMIN K

Vitamin K is crucial for the production of procoagulant proteins II, VII, IX, and X and the natural anticoagulants protein C and protein S. It is essential for the γ-carboxylation of these clotting factors, which is required for their functionality. Vitamin K itself is recycled, and when this process is blocked as with warfarin administration, these vitamin K-dependent factors are not produced in adequate amounts.

VITAMIN K DEFICIENCY BLEEDING

Vitamin K deficiency bleeding (VKDB) is classified as early, classical, or late. Classical VKDB usually occurs on the second to seventh day of life as a result of decreased synthesis of vitamin K-dependent factors. The etiology of vitamin K deficiency in newborns is multifactorial and includes reduction of storage, functional immaturity of the liver, lack of bacterial synthesis of vitamin K in the gut, and low amounts of vitamin K in breast milk.[32] Early VKDB is due to the placental passage of compounds that interfere with vitamin K metabolism, such as maternal anticonvulsant medications, vitamin K antagonists (warfarin), and drugs used to treat tuberculosis. This usually presents within 24 hours of life and may cause a cephalohematoma, intracranial hemorrhage, or bleeding from the umbilical stump. Late VKDB is again due to inadequate vitamin K content in breast milk and occurs almost exclusively in breastfed infants. The diagnostic evaluation of VKDB is straightforward as the prothrombin time (PT) is always prolonged, and the activated partial thromboplastin time (aPTT) is nearly always prolonged. Typically, the PT is prolonged out of proportion to the aPTT. The most effective management of VKDB is prevention, and all newborns should receive vitamin K at birth. Exceptions to the rule are those children with known G6PD deficiency in the family, as a significant number of these patients will develop frank hemolysis. In those children who present with frank bleeding due to VKDB, parenteral vitamin K and plasma or prothrombin complex concentrates can be given to arrest the blood loss.[25]

LIVER DISEASE

The liver is responsible for the synthesis of most pro- and anticoagulant proteins, and TPO, which stimulates platelet production. A disruption in liver function may have a significant impact on the coagulation system in neonates, exacerbating the already delicately balanced system. Laboratory abnormalities seen in liver failure are elevations in the PT, aPTT, and d-dimer, decreased fibrinogen, and a decreased platelet count. Furthermore, these patients have a functional defect in circulating platelets. The treatment of bleeding in liver failure is difficult due to the concomitant risk of fluid overload with large volumes of plasma and the risk of thrombosis. Correcting the coagulopathy involves replacement of vitamin K and infusion of fresh frozen plasma and platelets. In certain circumstances, off-label use of factor concentrates such as recombinant factor VIIa and prothrombin complex concentrate may be appropriate; however, it must be remembered that these concentrates carry a risk of thrombosis.

EXTRACORPOREAL LIFE SUPPORT

The coagulopathy associated with cardiopulmonary bypass and extracorporeal membrane oxygenation is multifactorial involving activation of the contact pathway, fibrinolytic pathway, tissue factor pathway, and an acquired platelet function defect.[28]

CONGENITAL HEART DISEASE

A significant number of children with congenital heart disease will have coagulation defects. It should be remembered, however, that in children with cyanotic heart disease with associated polycythemia, the elevation in PT/aPTT may be spurious and secondary to a sampling defect as there will be an alteration in the plasma anticoagulant ratio when the hematocrit is greater than 60%.[28]

Thrombotic states

The fetus and neonate are less efficient in generating thrombin, and thus, thrombotic disease in early childhood is rare and generally secondary to an acquired prothrombotic state or an inherited gene defect predisposing to clot formation. When it does occur in childhood, it can be fatal or associated with several sequelae such as amputation, organ dysfunction, and postphlebitic syndrome. The peak incidence for these thrombotic events is undoubtedly the neonatal period where the use of vascular access devices in tertiary care pediatrics is almost the norm. Preterm infants are at a greater risk than older children for thrombosis. When the delicate hemostatic balance is disrupted, in particular with vascular access devices and septicemia, the risk of developing thromboembolism increases significantly.

Acquired states

CENTRAL VENOUS CATHETER DEVICES

Central venous access devices have revolutionized the intensive care management of neonates. Unfortunately, thrombosis related to their placement continues to be a therapeutically challenging complication. It occurs in up to 10%

of neonates with central venous catheters; however, most of these are asymptomatic.[33] The presenting sign may be loss of patency of the catheter or swelling. Central venous lines or umbilical venous catheters associated with thrombus should be removed wherever possible. If the thrombosis is symptomatic, then a period of anticoagulation is necessary.[34] It should be remembered that although uncommon, death from venous thromboembolic disease in young children does occur. Therefore, early detection and adequate treatment are absolutely mandatory in this group of children.

RENAL ARTERY AND VEIN THROMBOSIS

Renal artery thrombosis in the neonatal period is associated with umbilical artery catheters (UAC). Risk factors for UAC-related thrombosis include hypoxia, hyperviscosity, sepsis, longer duration of UAC placement, the presence of calcium in the infused fluids, hypertonic saline, smaller umbilical artery caliber, and low UAC position. It may be difficult to diagnose, and hypertension and heart failure may be the presenting clinical features. There can be extension of the thrombus to other vascular beds such as the aorta. Recent clinical guidelines recommend high UAC placement to reduce thrombotic risk. Catheter removal, supportive care, anticoagulation, fibrinolytic therapy, and surgical approaches are all used in management of UAC thrombosis based on the severity of the clinical presentation.[35] Renal vein thrombosis (RVT) is more common than renal arterial thrombosis in the newborn period. It is associated with perinatal asphyxia, dehydration, sepsis, hypotension, cyanotic heart disease, polycythemia, babies born to diabetic mothers, and the presence of an indwelling umbilical venous catheter. The commonest presenting features are a palpable flank swelling, hematuria, and thrombocytopenia. Usually ultrasound will reveal renal enlargement with or without evidence of venous thrombosis. The use of anticoagulants and thrombolytic agents in this condition continues to be evaluated. There are no randomized controlled trials in the treatment of RVT. Either anticoagulant therapy or supportive care with close monitoring is an acceptable approach in unilateral RVT without renal impairment or clot extension into the inferior vena cava.[34] Acute complications of RVT include clot extension, adrenal hemorrhage, and acute renal failure. Survival rates in babies are as high as 80%, and renal status after recovery ranges from normal function to systemic hypertension and chronic renal insufficiency.

ACQUIRED PROTEIN C/S DEFICIENCY

Purpura fulminans in newborns is a rare life-threatening condition characterized by disseminated intravascular coagulation and hemorrhagic skin necrosis.[36] Affected infants present on the first day of life with ecchymosis, extensive venous and arterial thromboses, disseminated intravascular coagulation (DIC), and markedly low levels of protein C or protein S. It can result from inherited and acquired abnormalities of the protein C pathway. Acquired protein C deficiency can occur in conditions such as meningococcal septicemia. Early identification of the disorder and treatment with protein C replacement is essential to prevent serious morbidity and death.

ACQUIRED ANTITHROMBIN DEFICIENCY

Antithrombin inhibits coagulation. Its activity is potentiated by heparin. Severe congenital antithrombin deficiency is a rare autosomal recessive condition with a tendency to thrombosis in the neonatal period or early infancy. Acquired deficiencies of antithrombin have been associated with a large number of diseases such as DIC and microangiopathic hemolytic anemias (i.e., hemolytic uremic syndrome). Antithrombin concentrates are available and are the treatment of choice during the acute phase of the disease.

MISCELLANEOUS CONDITIONS

Other associations of neonatal thrombosis include NEC, respiratory distress syndrome, heparin-induced thrombocytopenia/thrombosis syndrome (extremely rare in neonates), antiphospholipid antibodies, extra corporeal membrane oxygenation (ECMO), hemolytic uremic syndrome, and birth asphyxia.

Inherited thrombotic states

Genetic defects within the protein C pathway account for the majority of cases of inherited thrombophilia.[37]

PROTEIN C AND PROTEIN S DEFICIENCY

Hereditary protein C (PC) and protein S (PS) deficiency (homozygosity or compound heterozygosity) are associated with a high venous thromboembolic risk at birth or in the first few months of life. The first clinical manifestation is usually skin purpura mainly affecting extremities, and in some cases, massive large vessel thrombosis can also be a presenting feature. Optimum therapy involves factor replacement (protein C concentrate or fresh frozen plasma in protein S deficiency) and heparin in the acute phase and oral anticoagulation in the long term.[37]

ANTITHROMBIN DEFICIENCY

Homozygous antithrombin deficiency is extremely rare and appears to be incompatible with life. Presentations of antithrombin deficiency in neonates include myocardial infarction at birth, aortic thrombosis, sagittal sinus thrombosis, and cerebral thrombosis.

OTHER INHERITED THROMBOPHILIAS

Several other inherited gene defects have been associated with increased propensity to clot formation, the commonest being activated protein C resistance and factor V Leiden, factor II gene variant (prothrombin^{G20210A}), and hyperhomocysteinemia.

Management

The primary goal of treatment in this age group is to prevent clot extension, which can result in end-organ damage.

Because the triggers for thrombosis, such as in-dwelling catheters, are usually transient, the recurrence risk is low. The approach to an individual infant must balance the risks of anticoagulation against the benefits of such treatment. The indications for use of anticoagulants in infants and children have changed dramatically over the past 20 years with major advances in tertiary pediatric care such as ECMO, cardiopulmonary bypass, hemodialysis, and the use of intra-arterial and intravenous indwelling catheters. The choice of anticoagulant is dependent upon the duration of anticoagulation and comorbidities such as renal failure. In the acute phase, either unfractionated heparin (UFH) or low molecular weight heparin (LMWH) is used. The advantages of UFH are its rapid reversibility and low cost. However, due to its unpredictable pharmacokinetic response, it requires frequent monitoring and dedicated central venous access. LMWH, on the other hand, is administered subcutaneously and requires less laboratory monitoring and dose adjustments. However, an antifactor Xa assay to monitor its anticoagulant effect must be readily available. It should be remembered that because the hemostatic system in infancy and childhood is constantly maturing, the anticoagulant effects of heparin are not predictable and therefore are deemed age dependent.

Surgical thrombectomy is rarely performed in neonates as this procedure is generally limited by the small size of blood vessel and the clinical instability of newborns with thrombosis.

As regards the new oral anticoagulants, argatroban, bivalirudin (both direct thrombin inhibitors), and rivaroxaban (factor Xa inhibitor), there is insufficient evidence to support their routine use in the management of thrombosis in neonates at this time.[34]

ANEMIA

Immediately following birth, all infants experience a decrease in hemoglobin (Hb) that results in varying degrees of anemia. There follows a progressive decline in Hb concentration during the 8–10 weeks following birth. In healthy term infants, clinical signs and symptoms of anemia are absent. This is termed "physiological anemia," and it is a direct consequence of physiologic processes related to birth and the transition to extrauterine life. It arises due to the switch in oxygen dependency from placenta-based to lung-based, and the increase in arterial Hb oxygen saturation that occurs when infants take their first breath, together with redistribution of blood flow following birth, and changes in red cell production due to the downregulation of erythropoietin production.[38] When the level of Hb is below the "physiological anemia" range, then a pathological neonatal anemia is present. While the majority of cases of anemia occurring in the neonatal period are acquired, a number of inherited disorders that involve gene defects of Hb, red cell membrane, and enzymes also present during this period. Anemia, whether it be acquired or inherited, may present as an incidental finding on a blood count performed for other reasons, with nonspecific signs of pallor, tachypnea, tachycardia, failure to thrive, jaundice, splenomegaly, or bleeding. If the anemia is due to a hemolytic process, then jaundice is almost always present. Like thrombocytopenia, the causes of neonatal anemia can be thought of in terms of decreased erythrocyte production and increased erythrocyte destruction.

Acquired anemia

ALLOIMMUNE HEMOLYTIC ANEMIA

Hemolytic disease of the fetus and newborn (HDFN) is the immune-mediated destruction of fetal red cells by a maternal antibody, formed when fetal red cells expressing a paternally derived red cell antigen enter the maternal circulation through a sensitizing event (e.g., via fetomaternal hemorrhage). The disease is mediated by the transplacental passage of a maternal IgG alloantibody. The spectrum of illness ranges from clinically insignificant to a severely affected anemic, hydropic fetus with jaundice, pleural and pericardial effusions, edema, and ascites. The D antigen from the Rhesus system (RhD) continues to be the most commonly identified antigenic stimulus for HDFN.[39] Other alloantibodies implicated in HDFN are anti-c and anti-Kell, which produce hemolysis in fetuses that carry the c and Kell antigens, respectively. The alloantibodies are acquired either as a result of prior blood transfusion or as a result of alloimmunization during the pregnancy itself. RhD negative mothers give birth to RhD positive fetuses in 0.9% of European ancestry pregnancies. In a first pregnancy, without prophylaxis, 15% of these mothers will become immunized against the RhD, and 0.7% will have infants affected with HDFN.[39] The diagnosis HDFN is confirmed by testing the blood group of the mother and baby together with the detection of maternal alloantibodies and a positive Coombs test. Thrombocytopenia may be present in those severely affected. Introduction of anti-D immunoglobulin prophylaxis has drastically decreased the prevalence of D antibodies and of anti-D mediated HDFN.

HDFN can also occur due to ABO blood group incompatibility. This tends to be more common and less severe than Rh incompatibility. It primarily affects group A or B newborns born to group O mothers. In this scenario, the Hb is often normal.

AUTOIMMUNE HEMOLYTIC ANEMIA

This is a very uncommon cause of neonatal anemia, and it arises when autoantibodies produced in the mother are directed against fetal red cell antigens causing hemolysis in a similar fashion to neonatal thrombocytopenia secondary to maternal ITP.

Infantile pyknocytosis

Hemolytic disease of the newborn has several generally well-known causes (Rh incompatibility, ABO incompatibility, red cell enzyme, and membrane defects), all of which are

discussed in more detail in individual sections of this chapter. A rare cause is infantile pyknocytosis. It can cause early neonatal jaundice with transient hemolytic anemia. It earns its name from the diagnostic red blood cell appearances (pyknocytes) on the peripheral blood smear. The cause remains unknown, but there is probably a familial susceptibility, which may promote the occurrence under certain circumstances. Whether the trigger is environmentally acquired or intrinsic remains to be determined. Its management is largely supportive consisting of phototherapy and red cell transfusion before the condition resolves spontaneously around 4–6 months of age.[40]

Blood loss

Anemia due to blood loss is the commonest cause of neonatal anemia in preterm infants. In most cases, this is iatrogenic and due to frequent blood sampling. Blood loss may occur peri-delivery due to fetomaternal hemorrhage, in a twin-twin transfusion syndrome, as a result of bleeding from a ruptured cord or abnormal placenta, or as a result of a giant cephalohematoma, an intracranial, gastrointestinal, or retroperitoneal bleed.

ANEMIA OF PREMATURITY

Anemia of prematurity (AOP) is an exaggeration of the normal physiologic anemia. Almost all preterm infants have anemia, and several factors contribute to this. Erythropoietin (EPO) levels in premature infants are low partly due to the liver, which remains as the primary site of EPO production. The liver is less sensitive to tissue hypoxia as a stimulus to EPO production than the kidney. As the fetus transitions from the hypoxic intrauterine environment to the oxygen-rich postnatal environment, EPO production is downregulated. EPO clearance is higher in neonates, and the increased growth rate compared to that of term infants is also an endogenous factor causing AOP. Exogenous factors contributing to AOP include iatrogenic blood loss due to frequent phlebotomy, nutritional deficiencies, inflammation, infections, and chronic illness.[41] The goal of treatment is to maintain adequate oxygen delivery to tissue. Transfusion has a clear indication in the case of blood loss or shock for the restoration of blood volume. In the remaining situations, it is imperative to take into account the clinical signs and physiologic needs of the infant as well as laboratory parameters when making the decision to transfuse.[41] The amount of allogeneic red cell exposure can be significantly reduced by limiting phlebotomy in the baby, administering folate and iron to all preterm infants, using erythropoietin appropriately, and complying with peer-reviewed transfusion guidelines.

Approach to management

Only severe or moderate neonatal anemia should be treated with blood transfusion, and this decision is made on clinical grounds as well as the Hb in accordance with peer-reviewed guidelines.[42] Hemolytic disease of the newborn (HDN) always resolves albeit it may take 1–2 months. In the first couple of weeks of life, the hemolytic process may be so brisk that the hyperbilirubinemia necessitates phototherapy to prevent kernicterus. Blood transfusion may also be required for infantile pyknocytosis and for neonatal anemia due to blood loss.

Inherited anemia

If the anemia is due to a hemolytic process, then jaundice is almost always present. When the hemolytic process is secondary to a red cell membrane defect, the abnormally shaped red blood cells are removed from the peripheral circulation, and the jaundice is usually accompanied by mild to moderate splenomegaly. Jaundice is also frequently seen in neonates with inherited red cell enzyme deficiencies, which can cause significant damage to the erythrocytes. Most of the hemoglobinopathies, apart from alpha-thalassemia major and hemoglobin-H (HbH) disease, do not cause neonatal jaundice.[43]

RED CELL MEMBRANE DEFECTS

These can be difficult to diagnose in the neonatal period especially in the case of the commonest type, hereditary spherocytosis (HS), where the classic blood film morphology of numerous spherocytes is indistinguishable from that seen in ABO incompatibility. Spherocytes are also seen in neonatal period with consumptive coagulopathy, birth asphyxia, and significant placental insufficiency. A positive family history of HS is very helpful in confirming the diagnosis, as osmotic fragility testing in this age group is not reliable and should be postponed until the child is between 6 and 12 months of age. It is predominantly a disease of autosomal dominant inheritance.

Hereditary elliptocytosis is also a disease of autosomal dominant inheritance caused by defects in various structural proteins, resulting in elliptical shaped red cells. The elliptocytes are unstable and nondeformable, and thus hemolyzed by the reticuloendothelial system. It is straightforward to diagnose by the presence of elliptocytes on the peripheral blood smear.[43]

Hemoglobinopathies

These are uncommon causes of anemia in neonates. As globin chain synthesis is in a state of flux between late fetal life and following birth, diagnosing hemoglobinopathy is fraught with difficulty in the neonatal period.

The hemoglobinopathies that cause significant neonatal anemia include homozygous α-thalassemia (Hb Barts hydrops fetalis) where there is deletion of all four α globin genes, and HbH disease where there is deletion of three of the regulatory α globin genes. In sickle cell syndromes, the Hb is normal in the neonate.[43]

Red cell enzyme deficiencies

These are usually straightforward to diagnose in the neonatal period. G6PD deficiency is an X-linked recessive disorder. It is

active in the metabolic pathway of the erythrocyte that protects the cell from free radical damage. Defects in G6PD can result in accumulation of damaging agents, leading to hemolysis. A G6PD assay should be performed in any cases of prolonged or severe jaundice unless there is an obvious alternative cause.

Pyruvate kinase is an enzyme in the erythrocyte that is responsible for cellular energy production. A deficiency of PK can therefore result in premature cell death. It is an autosomal recessive disorder. It is diagnosed by assaying red cell enzyme levels; PK assays should be performed in cases of unexplained hydrops, those with hemolytic anemia of unknown cause, and where there is a family history.[43]

DIAMOND–BLACKFAN ANEMIA

Diamond–Blackfan anemia frequently presents in infancy with an isolated macrocytic anemia due to pure red cell aplasia. It classically causes reticulocytopenia. About half of these infants also have a variety of congenital anomalies. It is inherited in an autosomal dominant fashion, and the first causative gene, RPS19, was discovered more than 15 years ago. To date, 13 mutations in ribosomal genes have been identified. Red blood cell transfusions are the mainstay of treatment with careful monitoring of iron status to avoid visceral iron overload. HSCT may be considered.[14]

MISCELLANEOUS

Other inherited conditions that can present as anemia in the neonatal period include Pearson's syndrome, congenital dyserythropoietic anemia, Aase syndrome, and osteopetrosis. Congenital infection in newborns, such as parvovirus, and acquired nutritional deficiencies, such as iron, copper, folate, B12, B6, vitamin A, vitamin C, and vitamin E deficiencies, can result in reduced red blood cell production.[44]

Polycythemia in the neonatal period

Polycythemia occurs in 1%–5% of neonates. It is more common in infants who are small for gestational age, who are large for gestational age, who are born to diabetic mothers, who have delayed cord clamping, who are the recipient in a twin-twin transfusion syndrome, and with chromosomal disorders.

NEUTROPHILS

Neutropenia can be secondary to decreased production of neutrophils, increased destruction, or a combination of these two mechanisms. Congenital neutropenia is characterized by chronic neutropenia due to a constitutional defect. Neonatal neutropenia occurs most frequently in association with maternal hypertension, sepsis, twin-twin transfusion syndrome, alloimmunization, and hemolytic disease.

Alloimmune neutropenia

Like HDFN, alloimmune neutropenia occurs as a result of the transplacental passage of maternal antineutrophil antibodies that attack a paternally derived antigen on fetal neutrophils. In a well-appearing infant with persistent isolated neutropenia, an immune-mediated etiology should be considered. The condition is diagnosed by the demonstration of antineutrophil antibodies in the mother and the baby. It is confirmed by human neutrophil antigen genotyping of the mother and the father.[45] In general, the outcome is good with resolution of the neutropenia by 3 months after birth. Treatment is still a matter of debate, but granulocyte colony-stimulating factor (G-CSF), IVIG, corticosteroids, and antibiotics have all been used.

Autoimmune neutropenia

Neonatal autoimmune neutropenia results from the transmission of preexisting maternal antineutrophil autoantibodies into the fetus. This can occur in autoimmune conditions such as maternal systemic lupus erythematosus.

Autoimmune neutropenia of infancy

This is a transient autoimmune phenomenon where the infant's own immune system produces an antineutrophil antibody.

Miscellaneous

Various other conditions can lead to neutropenia in the neonate. In a critically ill infant, sepsis should be part of the differential diagnosis. NEC can lead to neutropenia. Copper deficiency is a consideration in infants with short bowel syndrome who are dependent on parenteral nutrition. Congenital bone marrow failure syndromes can rarely present early, and the presence of other phenotypic anomalies should raise this possibility. Neutropenia in association with cardiomyopathy and skeletal myopathy in a male infant is seen in Barth syndrome. Inborn errors of metabolism usually present late in the first week of life and beyond. Certain drugs may be implicated in neonatal neutropenia (thiazides, β-lactam antibiotics).[46]

Severe congenital neutropenia

Severe congenital neutropenia (SCN) is a heterogenous group of disorders characterized by severe neutropenia, maturation arrest of bone marrow myeloid precursors, and recurrent bacterial infections. Diagnosis is made on bone marrow biopsy and confirmed with genetic testing. Originally described by Kostmann with autosomal recessive inheritance, genetic discovery has broadened the spectrum of SCN inheritance. Autosomal dominant, X-linked, and sporadic causative mutations exist with 50%–60% of patients having a mutation in the neutrophil elastase gene ELA2 (ELANE). Other mutations reported to cause SCN include mutations in the HAX1, G6PC3, WAS, GFI1, and JAGN1.[14] Before the introduction of modern therapies, SCN was highly fatal. Treatment with G-CSF is standard, although

development of myelodysplastic syndrome or leukemia is a concern with long-term use. For the minority who fail to respond adequately to G-CSF, HSCT should be considered.[14]

Shwachman–Diamond syndrome

Shwachman–Diamond syndrome (SDS) usually presents with isolated neutropenia that may progress to bone marrow failure. It is characterized by exocrine pancreatic insufficiency leading to malabsorption and steatorrhea in the first few months of life. Infants develop growth retardation, frequent bacterial infections, and failure to thrive. They have pathognomonic skeletal abnormalities including metaphyseal widening and dysostosis. The hematological features of SDS vary, but typically, severe intermittent neutropenia is the initial finding. It is inherited in an autosomal recessive fashion, with germline mutations in the SDS gene accounting for about 95% of patients. Management is multidisciplinary in approach based on the affected organ systems.[14]

HEMATOLOGICAL DISORDERS IN THE NEONATE WITH DOWN SYNDROME

Down syndrome (DS) is the most common chromosomal abnormality in the live newborn. It is caused by an extra whole or partial copy of chromosome 21. A number of hematological abnormalities are recognized in neonates with this condition. Up to 80%, 66%, and 34% of newborns with DS have neutrophilia, thrombocytopenia, and polycythemia, respectively.[47]

In general, these abnormalities are mild, the clinical course is benign, and they spontaneously resolve.

Transient myeloproliferative disorder (TMD) is a disease entity that is unique to DS or those with T21 mosaicism and is defined as the morphologic detection of blasts in the peripheral blood in newborns with DS less than 3 months of age. Typically, it is detected within the first week of life and spontaneously resolves within 6 months of birth. It is estimated to occur in up to 10% of all newborns with DS. TMD has a variable presentation in the fetus and newborn from mild disease to disseminated leukemic infiltration with pleural and pericardial effusions and fulminant hepatic fibrosis. However, it commonly presents with the isolated finding of circulating blasts without any clinical symptoms. It can cause neonatal death secondary to liver failure, heart failure, sepsis, hemorrhage, hyperviscosity, and DIC. All TMD blasts have a somatic mutation in the X-linked GATA-1 gene. TMD should be considered in the differential even if DS is not suspected because it can occur in neonates who are mosaic for trisomy 21. Most neonates with TMD do not need treatment. The outcome for those who have progressive life-threatening signs such as hepatic, renal, and/or cardiac failure may be improved by the administration of low-dose cytosine arabinoside.

Identifying TMD in the neonatal period is important since 20%–30% of cases later develop acute myeloid leukemia.[48]

Genetics in neonatal surgical practice

ANDREW GREEN

NATURE AND STRUCTURE OF A GENE

Genetics is traditionally defined as the science of biologic variation and has been a scientific discipline for over 100 years. Human genetics makes up a large part of the field of genetics, but the principal laws of genetics are universal, and apply equally to all species, including humans. Mendel's studies in the nineteenth century were originally felt to have no relevance to humans, and it is only in retrospect that their importance can be seen. Many of the principles of genetics were discovered through the study of smaller organisms, such as bacteria, yeast, and fruit flies. The basic genetic mechanisms of cell division, development, and differentiation happen in the same way in widely divergent species. Therefore, it is impossible to look at human genetics in isolation, and there are large amounts of information from lower species that have bearing on human disorders. The study of the genetics of small organisms has had a profound impact on our understanding of human development and of how human diseases develop. It is likely that such basic science will continue to contribute significantly to the understanding of human genetic disease. This chapter will attempt to outline the basic elements of genetics, describe the types of genetic tests now available to help in neonatal diagnosis, and give an approach to the diagnosis of congenital abnormalities.

The basic unit of inheritance for any species is the gene. The original concept of a gene arose long before the relationship between genes and nucleic acids was ever understood. A gene was considered to be a stable heritable element, which conferred a particular property or phenotype onto an individual organism. This element was passed on to subsequent generations of a particular species, and the nature of the phenotype varied according to the nature of the gene. The concept of dominant and recessive traits, which will be discussed later, was derived from studies of inheritance patterns, long before the molecular basis of the gene was understood.

A gene can also be considered in another way as a specific length of deoxyribonucleic acid (DNA), which encodes a particular function, in most cases the synthesis of a protein. This also is a stable heritable unit. Each cell in an organism, regardless of its function, has the entire set of genes for that particular organism, but only a proportion of those genes will be active. DNA is found in the nucleus of every cell of an organism as a double helix (Figure 22.1).

Each strand of the double helix has a backbone of alternating phosphate and deoxyribose sugar molecules, with the sugars attached to the 5′ and 3′ hydroxyl groups of the phosphate group. Attached to the sugar molecule, lying within the helix, is one of four nitrogen-containing nucleic acid bases. Two of these bases, adenine (A) and guanine (G), are purines, and two are the smaller pyrimidines, cytosine (C) and thymine (T). The A and T bases pair together by hydrogen bonding, and the G and C bases similarly pair by hydrogen bonds (Figure 22.2). The two strands of the double helix are held together by paired A–T or G–C bases of opposite strands of the double helix. The DNA strand can be read in only one direction from 5′ (left hand) to 3′ (right hand). The two strands of DNA are complementary to each other, and the sequence of one strand can be predicted from its opposite. If one strand reads 5′-CAGCGTA-3′, then the opposite strand must read 5′-TACGCTG-3′. The double-stranded sequence would then be written as follows:

5′-CAGCGTA-3′
3′-GTCGCAT-5′

The simplicity of the double helix structure allows for several important functions for DNA.

Firstly, huge amounts of information can be stored in the strand of DNA. If a molecule of DNA is 1 million bases long, then there are $4^{1,000,000}$ possible sequences for that stretch of DNA. A genome is the complete DNA sequence of an organism. In humans, the estimated genome size is 3×10^9 base pairs (bp). The human genome contains a huge

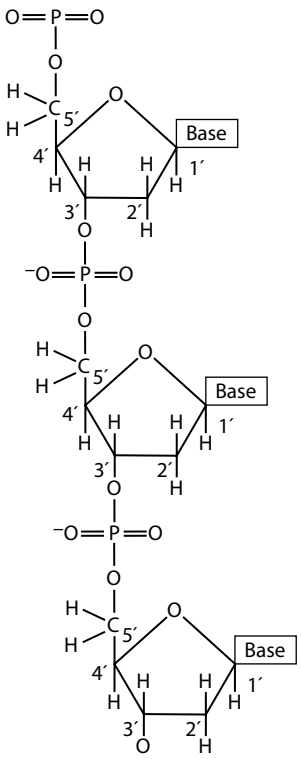

Figure 22.1 Structure of a DNA chain. The deoxyribose and phosphate residues are linked to form the sugar-phosphate backbone of DNA.

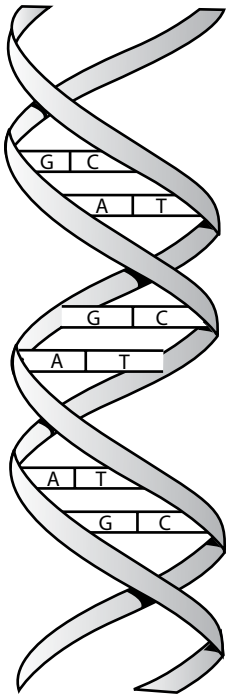

Figure 22.2 Double-helix structure of DNA. The double helix of deoxyribose and phosphate molecules is held together by paired purine and pyrimidine bonds.

amount of coded information, of which as yet only a small part is known.

Secondly, the double helix provides a framework for DNA replication. One strand of DNA acts as a template for the synthesis of a new strand of DNA. The double helix unwinds, allowing DNA replication enzymes access to the template strand of DNA. The replication system builds a new strand of DNA based on the template. The new double helix formed as a result will contain one original strand and a newly synthesized complementary second strand. This is the basic mechanism of DNA replication in all species.

Thirdly, the double helix provides a basis for repair of damaged DNA. A damaged base can be replaced, knowing its complementary base is present on the opposite strand. Damage to the sugar-phosphate backbone can also be repaired using the opposite strand as a template.

DECODING THE INFORMATION IN DNA

About 90% of the DNA in the human genome does not code for any specific property. Only about 10% of the genome actually contains coding information in the form of a gene. In simple terms, the genetic code in DNA is transcribed into a molecule called messenger RNA (mRNA). The mRNA is then translated into a protein, which carries out the function encoded by the specific DNA.

A gene has several distinct elements (Figure 22.3). The major part of the gene is divided into coding regions, called exons, and noncoding regions, called introns. Just before (5′) the first exon, there is a promoter that indicates where transcription of a gene should start. There can be several promoters for one gene, and different promoters can be used according to the tissue in which the gene is being expressed; in other words, the promoter is tissue specific. Further 5′ of the promoter, there can also be enhancers or suppressors, which can increase or decrease the level of transcription of the gene. Not all of the mRNA will code for protein, as some exons will code for mRNA that does not directly encode protein. These areas, known as untranslated regions, can be either at the start (5′) or the end (3′) of the mRNA.

To express the DNA code, mRNA is used. There are several different types of RNA, but mRNA is the most important in decoding DNA. There are three differences between RNA and DNA. Firstly, the sugar backbone of RNA contains ribose rather than deoxyribose. Secondly, mRNA exists as a single strand and remains more unstable. Thirdly, in RNA, the base uracil (U) is used instead of thymine (T), whereas the other three nucleic acids remain the same.

The DNA code in most genes is expressed as a protein, which is a peptide made of the building blocks of individual amino acids. Each amino acid is coded for by a sequence of three DNA bases, known as a codon. For some amino acids, there is more than one codon (see Table 22.1). A long series of DNA codons in a gene will thus code for an entire protein. The mRNA codons coding for amino acids are identical to DNA codons, with the substitution of uracil (U) for

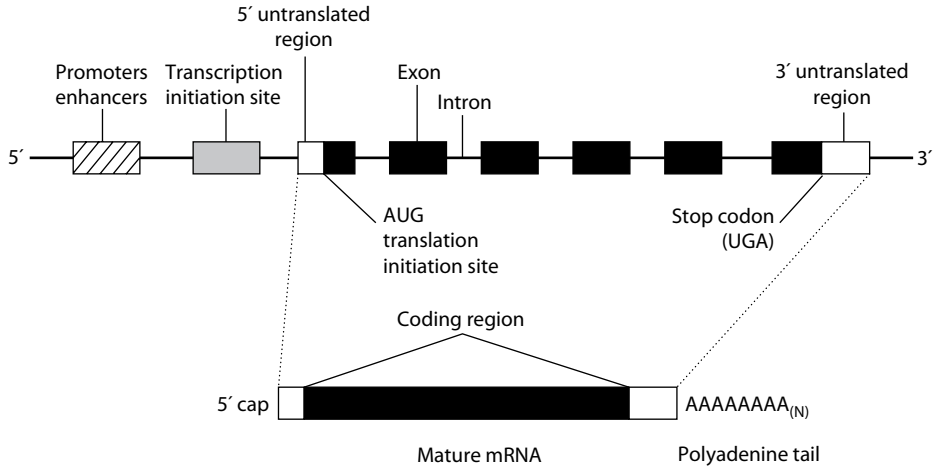

Figure 22.3 Idealized gene.

thymine (T). There is a tightly controlled mechanism for the generation of protein from a DNA template.

To decode a gene into protein, the DNA is first transcribed into mRNA. A strand (the "sense" strand) of the DNA double helix is used by the enzyme RNA polymerase to synthesize a complementary strand of mRNA. Transcription of mRNA starts from the 5′ end of the first exon of the gene until the end of the most 3′ exon. The intervening introns are initially included, and the first molecule is known as pre-mRNA. The intronic RNA sequences are spliced out, and a 3′ polyadenine tail is added, producing mature mRNA. The mature mRNA is then transferred from the nucleus to the ribosome to be used as a template for the production of protein. The mature mRNA has both 5′ and 3′ untranslated regions.

Protein synthesis does not begin at the 5′ end of the mRNA, but at the first 5′ AUG codon, which codes for the amino acid methionine. Protein translation stops at the first truncation codon (usually UGA) thereafter (Figure 22.3). In the ribosome, amino acid-specific RNA molecules, called transfer RNAs, bind a free molecule of their specific amino acid. The binding is carried out by an anti-codon in the tRNA, which is complementary to the mRNA that codes for that specific amino acid. Using its anti-codon, the tRNA binds the specific mRNA codon for its amino acid. By complex machinery, the amino acid is then added to a growing peptide chain, which will eventually form the mature protein (Figure 22.4). The 5′ end of the mRNA corresponds to the NH_2 (amino terminus) of the protein, and the 3′ end of the mRNA corresponds to the COOH (carboxyl terminus)

of the protein. Many proteins in higher species are modified after translation by the addition of phosphate or lipid groups.

CHROMOSOMES AND CELL DIVISION

To successfully package vast amounts of DNA into each cell nucleus, it must be compressed and compacted. The first coiling of DNA is in the form of the double helix. The negatively charged DNA double helix is then bound tightly to and wound 1.65 times around a core of eight positively charged *histone* proteins to form a *nucleosome*. The addition of another histone completes the second winding of DNA about the histone core to form a *chromatosome*. These units stack up and form loops of approximately 300 nm. These are stacked, compressed, and folded into fibers of 250 nm wide. These fibers are then tightly coiled to form a *chromatid*. Two sister chromatids make up a single chromosome, joined by a *centromere*. The centromere represents a division along the chromatids in a chromosome, creating a short arm "p" and a long arm "q."

Nonsex chromosomes are termed *autosomes*. Humans are *diploid*, carrying two copies of each autosome. The normal human chromosome complement in nonsex cells is 46, comprising 22 pairs of autosomes and two sex chromosomes. Females carry two copies of the X chromosome, while males have one copy each of chromosomes X and Y. Each member of a pair of autosomes contains the same genetic information. The two X chromosomes in a female contain the same genetic information. The X and Y chromosomes in a male only have a small amount of genes in common, with the Y chromosome bearing a number of genes encoding male-specific genetic information. A normal human metaphase karyotype is shown in Figure 22.5.

Cells involved in production of gametes are termed germ cells, while all other cells are termed somatic cells. The process of cell division and replication in somatic cells is termed mitosis. During this process, the parent cell should divide to produce two genetically and morphologically identical daughter cells. This process allows the formation of a complete human being from a single fertilized egg, and is the process by which cells are constantly renewed. Genetic variation can arise as a result of spontaneous mutation during this process.

Mitosis is one short period during a carefully programmed cell cycle (Figure 22.6). Before commencing the process of cell division (M phase), the cell is said to be in interphase transitioning through different stages of DNA replication, chromosome elongation, and rest. After a mitotic event, nondividing cells enter a phase of rest (G0), while dividing cells commence a new cell cycle and enter the G1 phase. Upon entering G1, the cell grows and commences replication of DNA (S phase). Following the S phase, the cell enters G2, a resting phase, in preparation for cell division, thereafter entering the M phase.

The M phase itself comprises a number of stages—prophase, metaphase, anaphase, telophase, and cytokinesis—and involves interplay between the chromosomes and specialized tubulin-based microtubules. The mitotic spindle is composed of microtubules and microtubule-associated proteins. In metaphase, the condensed chromatids line up along the equatorial plane of a cell. In anaphase, spindle tubules extend from the centrioles located at each pole of

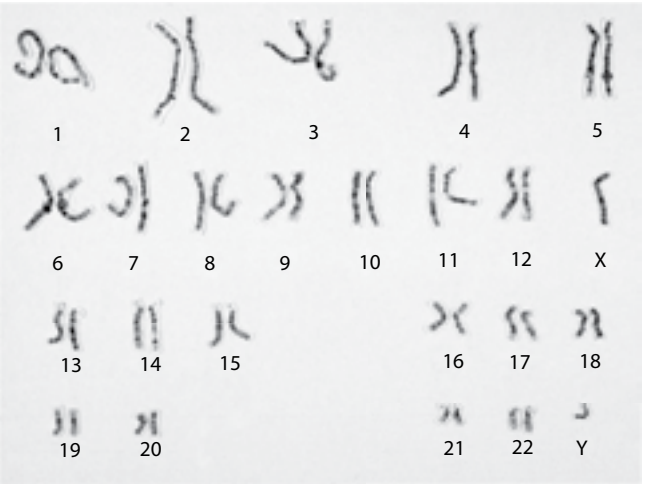

Figure 22.5 Normal male karyotype.

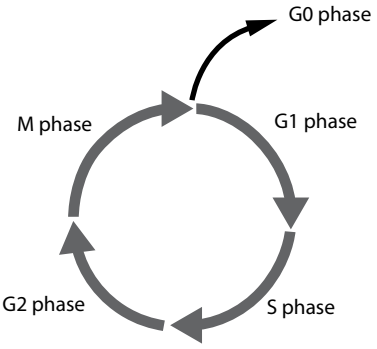

Figure 22.6 Cell cycle.

the cells to the chromosomal centromeres. As these tubules move back toward the centriole, they pull one chromatid with them to opposite poles of the cell. The splitting of the centromere and separation of sister chromatids toward two poles is termed anaphase. By the telophase, the chromatids have reached opposite poles of the dividing cell. The nuclear membrane starts to reform, completing mitosis, and the cytoplasm also divides. Cell division is completed by cytokinesis, during which the parent cell completely divides into two identical daughter cells.

Meiosis is a specific form of cell division, required to produce gametes (sperm or oocyte). Gametes are haploid, with only one copy of each chromosome, to give a total complement of 23 chromosomes. The process of fertilization results in the formation of a new diploid organism from two haploid gametes. In the parent, formation of a haploid gamete requires two successive divisions of a specialized diploid germ cell, namely the primary oocyte or primary spermatocyte, in stages termed *meiosis I* and *meiosis II*. In males, the products of these two divisions are four spermatozoa. In females, the products of meiosis I are one secondary oocyte and a small *polar body*. Meiosis I may last several years, arrested from the first stage in the fetus until the completion of meiosis I at puberty. The secondary oocyte then undergoes *meiosis II* to produce a large mature egg cell and second polar body.

Meiosis I produces two haploid daughter cells, with a total of 23 chromosomes each. One daughter cell contains the paternal homolog of each chromosome pair, and the maternal homolog is contained in the other daughter cell. This process is random for each chromosome pair, and each gamete has different contributions from paternal and maternal lineages depending on which chromatid of each of the 23 chromosome pairs ended up in that particular daughter cell. This independent assortment ensures variation between gametes, and therefore between fraternal siblings. Furthermore, *crossing over* of genetic material from one chromatid to another is possible. Approximately one or two crossovers occur per chromosome per meiosis. This process introduces further genetic diversity.

The first phase of meiosis I, *prophase I*, is similar to prophase in mitosis. Homologous chromosome pairs align. This process facilitates recombination between chromatids, and between maternal and paternal homologs, allowing *crossing over* of material. In *metaphase I*, homologous chromosomes line up opposite each other along the metaphase plate. In *anaphase I*, these chromosome pairs are separated, moving to opposite cellular poles. Within each chromosome, sister chromatids remain united during this process. In *telophase I*, nuclear envelopes form to enclose the two separate groups of chromosomes. The cytoplasm around the two nuclei is then divided to form two distinct haploid daughter cells, each with only one set of chromosomes ($n = 23$), in a process called *cytokinesis*. Failure of the daughter cells to completely separate is termed *nondisjunction*, which can manifest as chromosomal aneuploidy in offspring. The frequency of nondisjunction events increases in direct relation to increasing maternal age, and is a common cause of chromosomal syndromes such as Down syndrome or Edward syndrome.

Meiosis II is analogous to mitotic division of each of the haploid daughter cells. Chromatids condense again in *prophase II* and line up along the axis of the dividing cell in *metaphase II*. The chromatids then separate, passing to opposite ends of the cell in *anaphase II*. The chromatids elongate into thin strands in *telophase II*. Meiosis II concludes with cytokinesis, resulting in four new cells that represent precursor gametes.

In males, all four cells are identical precursor spermatogonia. In females, although division of genetic material between the four daughter cells is equal, the division of cytoplasm in both cytokinesis I and cytokinesis II is unequal. In meiosis I, this results in one primary oocyte and smaller polar bodies, and in meiosis II, one secondary oocyte and three polar bodies. These polar bodies generally cannot be fertilized and often apoptose spontaneously. Spermatogenesis in males begins at puberty, producing four gametes per spermatocyte on a continuous basis throughout a male lifetime. In females, the process of oogenesis begins even before birth, arrested at meiosis I until puberty, at which stage some arrested oocytes proceed through the first stages of metaphase II. Only one ovum will be produced per oocyte.

CHROMOSOME ANOMALIES AND ANALYSIS

Chromosome abnormalities can broadly be classified into abnormalities of chromosome number or a rearrangement of a normal number of chromosomes. Problems can arise clinically if there is addition or loss of vital genetic material, or indeed if genetic material is moved in such a way that it loses proximity to regulatory regions.

Abnormalities of chromosome number are relatively common, but many are not recognized, as they may result in the early loss of a pregnancy. Triploidy (69 chromosomes) and tetraploidy (92 chromosomes) are relatively common causes of early pregnancy loss. Trisomy, the presence of a single extra chromosome (47 chromosomes), is also a common cause of miscarriage. Specific trisomies may be compatible with life, the commonest being trisomy 21 (Down syndrome), trisomy 13 (Patau's syndrome), and trisomy 18 (Edwards' syndrome). The most common cause of these trisomies is autosomal nondisjunction in meiotic division of

the oocyte. In nondisjunction, the chromatids in question fail to separate, resulting in an extra chromosome in one oocyte and no chromosome in the opposite gamete (nullisomy). Nondisjunction tends to occur more frequently with increasing maternal age. Nondisjunction can occur in the male germline, but rarely produces viable offspring.

Fertilization of the oocyte with the extra chromosome will therefore result in an embryo that is trisomic for that particular chromosome. Conversely, fertilization of a nullisomic oocyte will result in an embryo that is monosomic for the chromosome in question; and generally, this is not compatible with life.

There are numerous types of chromosome rearrangements, the commonest of which are shown in Figure 22.7. Inversions refer to rotation of a section of a chromosome by 180°. Pericentric inversions (involving the centromere) and paracentric chromosome inversions (not crossing the centromere) are usually balanced, without any loss or gain of genetic material. These types of chromosomal anomalies may be inherited without any phenotypic effect. Paracentric inversions are usually associated with a low risk of producing a live-born with an unbalanced karyotype, but this risk is higher for inversions involving the centromere. Insertions, duplications, deletions, isochromosomes, and ring chromosomes are all usually aneuploid and associated with significant clinical abnormalities.

Reciprocal translocation refers to the exchange of genetic material from one arm of a chromosome in return for genetic material from a different chromosome. Reciprocal translocations are usually balanced, without clinical effect; but carriers of such translocations do carry the risk of producing offspring with an unbalanced number of chromosomes. Unbalanced reciprocal translation carriers can have a severe clinical phenotype.

Robertsonian translocation is a particular type of translocation involving chromosomes that bear very short p arms with little genetic information, termed *acrocentric* chromosomes (13, 14, 15, 21, and 22). In Robertsonian translocations, the two q arms of any of these acrocentric chromosomes fuse, with loss of the two respective p arms. Robertsonian translocations are one of the commonest human chromosome translocations, the most common of which is between chromosomes 13 and 14. Balanced Robertsonian translocations are of no clinical consequence to the carrier directly, but may have profound consequences for their offspring. A Robertsonian translocation involving chromosomes 14 and 21 is shown in Figure 22.8. Those who carry a Robertsonian translocation involving chromosome 21 may be at significantly higher risk of having a child with Down syndrome as an unbalanced product of the translocation. The same applies to a lesser extent for those carrying a Robertsonian translocation involving chromosome 13, and a subsequent risk of a child with Patau's syndrome.

Analysis of chromosomes involves close interrogation of chromosome number and structure, and can be carried out in two main ways: by karyotype or by array comparative genomic hybridization (array CGH, microarray).

As part of karyotype analysis, dividing cells in culture must be examined. These cells are usually lymphocytes (collected in lithium heparin), amniotic fluid cells, or fibroblasts. Cells are arrested in the metaphase stage of mitosis and stained in such a way that the chromosomes are easily

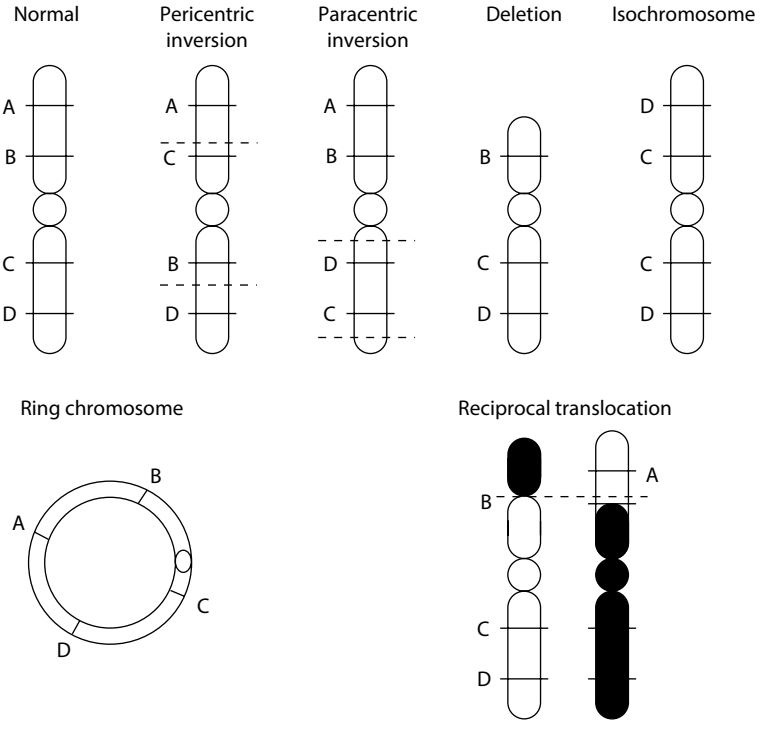

Figure 22.7 Different types of chromosome anomaly. A–D represent notional chromosomal loci.

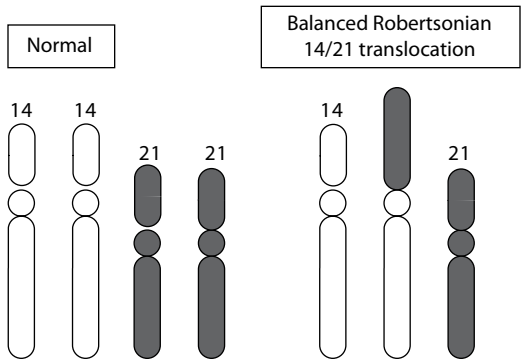

Figure 22.8 Robertsonian translocation.

visualized. The usual technique used is G-banding (using a Giemsa stain), which gives a characteristic positive and negative banding pattern to each chromosome. Each chromosome has a constriction, called a centromere, dividing the chromosome into a short arm (p) and a long arm (q). Each arm has a number of prominent bands, which can then be subdivided into smaller bands. The gene for the ABO blood group is localized to chromosome 9q34. The gene thus lies in the fourth subband from the centromere (q34) of the third band from the centromere (q34) on the long arm (q34) of chromosome 9 (9q34).

Karyotype analysis is useful for the analysis of chromosome structure as well as number, and can identify translocations or inversions, which may be missed by other types of chromosome studies.

The nomenclature for reporting a chromosome analysis is strict and needs to be read carefully. A karyotype is reported initially as the number of chromosomes, regardless of whether those chromosomes are normal or not, followed immediately by the sex chromosome, completing a normal report. Any abnormalities are added after the sex chromosomes. A normal male karyotype is reported as **46,XY**. A male with nondisjunctional Down syndrome will have the karyotype **47,XY, +21**, an extra unattached chromosome 21. In the case of a Robertsonian translocation between chromosomes 14 and 21, the parent will have a balanced complement, with inconsequential loss of 14p and 21p and fusion of 14q and 21q, leaving a total complement of 45 chromosomes. Her karyotype will be reported as **45, XX, t(14;21)**. She is at risk of having a child with an unbalanced translocation and Down syndrome. In this case, her child will have 46 chromosomes, but this includes three copies of 21q, leading to Down syndrome. A son with this rearrangement will have a karyotype 46,XY, der (14;21), +21.

However, recombinant DNA technology has allowed new techniques for chromosome analysis based on the hybridization of fluorescently labelled fragments of DNA to the DNA of chromosomes, prepared in a standard fashion, immobilized on a glass slide. The slides can then be visualized by eye using a fluorescent microscope, or indirectly by generating an image of the hybridization on a computer. This technique is known as fluorescent in situ hybridization (FISH). The information that can be gained from this technique depends on the origin of the fragments of DNA hybridized to the chromosome preparation. Labelled whole chromosome "paints," consisting of DNA exclusively from one chromosome, are now commercially available. For example, whole chromosome paints can be used to identify the origin of extra chromosomal material that cannot be identified using G-banding techniques. Whole chromosome paints are also helpful in determining the origin of subtle complex translocations. It is also now technically possible to use a chromosome 21 paint on uncultured cells in interphase to look for trisomy 21. A cell would show three fluorescent nuclear dots, representing three chromosomes 21, as opposed to two in the normal situation.

Fluorescently labeled small DNA fragments, corresponding to 40–50 kb of DNA from a specific chromosomal region, can also be hybridized to metaphase chromosomes. Chromosomal deletions that cannot be detected within the resolution of conventional cytogenetic analysis can be detected by the FISH method. A normal karyotype will give two hybridization signals: one from the same part of each chromosome. A karyotype containing a submicroscopic chromosomal deletion involving the segment of the chromosome corresponding to the 50 kb DNA fragment will only give one hybridization signal. An example would be the submicroscopic deletion of chromosome 22q11, which occurs in most cases of the Di George spectrum, which can only be seen by FISH analysis of chromosomes.

GENOMIC ARRAY ANALYSIS

Array comparative genomic hybridization (array CGH or microarray) has become increasingly important in diagnosis of chromosomal anomalies. As part of this analysis, probes corresponding to tens of thousands of recognizable pieces of DNA are applied to slides of silicone or glass (microarrays). The patient DNA and a reference DNA sample are differentially labelled and are then applied to this microarray. Differences in the ratio of hybridization between the probes and patient DNA compared to that of the probes and reference genome are interrogated to identify loss or gain of genetic material. This genomic array technology can permit analysis of thousands of individual loci simultaneously and gives chromosome analysis at a resolution at least 100 times greater than conventional G-banded chromosome analysis. Array CGH is sometimes referred to as a "molecular karyotype." Genomic array technology will identify pathogenic chromosomal anomalies in 20%–25% of infants in whom no underlying diagnosis had been identified previously. There is a drawback in that genomic array technology will often find genetic variants of unknown significance (VUS), and the current understanding of the role of such variants in disease pathogenesis is limited. Genomic array technology is now becoming available in an increasing number of diagnostic cytogenetic laboratories. It is likely to replace standard G-banded chromosome analysis for a wide variety of indications over the next few years.

Single nucleotide polymorphisms (SNPs) refer to changes in a single base pair of DNA and are the most frequently occurring form of human variation, occurring once every 300 bases. The human genome contains millions of SNPs, and this knowledge can be applied to development of SNP microarrays. In this case, hybridization of the patient DNA to probes for the different alleles at known SNPs is analyzed. Utilities of SNP microarrays above conventional microarrays include detection of uniparental disomy, an unusual situation in which the two copies of a chromosome in an offspring are derived from only one parent.

PATTERNS OF INHERITANCE

Single-gene disorders have one of three principal modes of inheritance: autosomal dominant, autosomal recessive, and X-linked recessive. Other rare forms of inheritance include X-linked dominant and mitochondrial disorders, as well as disorders due to abnormalities of genetic imprinting. Disorders caused by inheritance of unstable elements of DNA are now increasingly being recognized (see later).

Autosomal dominant inheritance

Autosomal dominant disorders are characterized by vertical transmission from parent to child, and the hallmark of these conditions is that male-to-male transmission of the disease is possible (Figure 22.9).

Those affected with an autosomal dominant disorder have an alteration in one or other copy of their two genes responsible for that condition. Each child of a person with an autosomal dominant disorder has a 50:50 chance of inheriting the gene responsible for the condition from its parent.

There are many examples of autosomal dominant disorders, including neurofibromatosis 1 and 2, familial adenomatous polyposis coli, myotonic dystrophy, and Huntington's disease. There can often be variability in both *expression* and *penetrance* of autosomal dominant disorders. *Penetrance* refers to the development of a phenotype in an individual as a consequence of a particular genotype, while *expressivity* or *expression* refers to the severity of this phenotype. For example, neurofibromatosis 1, an autosomal dominant condition, will almost always manifest in someone who has an altered neurofibromatosis 1 gene. This means that the condition has almost complete penetrance. However, different people can manifest the condition in different ways, with some people showing mild skin lesions and others with severe intracerebral complications. This means that the expression or expressivity of the condition is very variable. In contrast, only 80% of those who have a single altered gene for the rare hereditary form of retinoblastoma will actually develop an eye tumor. The penetrance in this situation is 80%, but the expression of the altered gene is consistent, as manifested by a retinoblastoma.

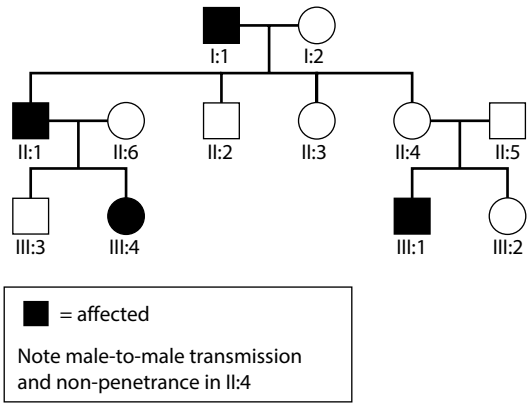

Figure 22.9 Autosomal dominant inheritance.

Table 22.2 Autosomal dominant disorders in neonatal surgical practice

System affected	Condition
Gastrointestinal	Hirschsprung's disease (some cases)
	Beckwith–Wiedemann syndrome with exomphalos (some cases)
	Pyloric stenosis (some cases)
Genitourinary	Vesicoureteric reflux
Skeletal	Stickler's syndrome
	Most craniosynostosis syndromes
	Achondroplasia
	Osteogenesis imperfecta
	Limb reduction defects (some cases)
Cardiac	Holt–Oram syndrome
	Noonan's syndrome
	22q11 microdeletion syndrome
Other	Retinoblastoma

Autosomal dominant disorders are not commonly seen in neonatal surgical practice. A list of the more frequent conditions is outlined in Table 22.2.

Autosomal recessive inheritance

When a child is diagnosed with an autosomal recessive disorder, both copies (alleles) of a particular gene responsible for the condition are altered. Generally, in this case, the child has inherited one mutated allele from each parent, meaning that the parents are unaffected *carriers* for the condition, with one normal and one altered gene. Carriers of autosomal recessive traits generally do not manifest features of the condition, as their normal copy of the gene can compensate for loss of function of the mutated allele. Two of an affected child's four grandparents are also carriers, and it is likely that many of the child's relatives are also unknowingly carriers (Figure 22.10). In most cases, being a carrier for an autosomal recessive condition has no effect on that person.

When both parents are carriers for an alteration in the same gene, then there is a 25% or 1 in 4 chance for each of their children to be affected by the condition. The risk of a healthy carrier sibling of having a child with the same

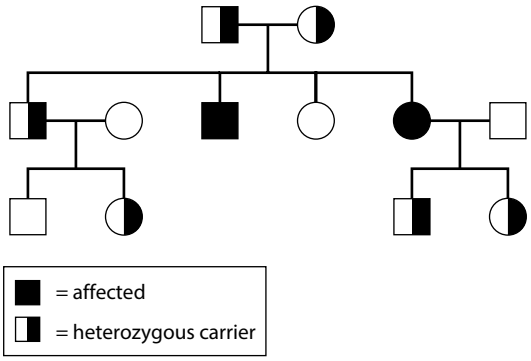

Figure 22.10 Autosomal recessive inheritance.

Table 22.3 Autosomal recessive disorders in neonatal surgical practice

System affected	Condition
Metabolic	Cystic fibrosis
	α-1-antitrypsin deficiency
Skeletal	Short-rib polydactyly syndrome
	Jeune's syndrome
	Robert's syndrome
Genitourinary	Infantile polycystic kidneys
	Meckel–Gruber syndrome
Endocrine	Congenital adrenal hyperplasia

condition depends on the chances of that sibling's partner also being a carrier. All children of a person with an autosomal recessive disorder will automatically be carriers. The chances of any of these children being affected will depend upon whether the other parent is a carrier for an alteration in the same gene.

Autosomal recessive disorders are commonly encountered in neonatal practice, and the nature of the disorder depends on the population being seen. Each regional population has its own recessive disorder, where the frequency of carriers for that disorder is the highest. For instance, cystic fibrosis is a very common autosomal recessive disorder in Western Europe, whereas sickle cell anemia is the commonest autosomal recessive disorder in West Africa. Common examples of autosomal recessive conditions include cystic fibrosis, sickle cell anemia, several of the mucopolysaccharidoses, beta-thalassemia, spinal muscular atrophy, and congenital adrenal hyperplasia (Table 22.3). Prenatal diagnosis is available for many of these conditions.

X-linked recessive inheritance

In X-linked recessive inheritance, the condition affects almost exclusively males, and females can be carriers (Figure 22.11). The classic examples of such conditions are hemophilia A and B, Duchenne and Becker muscular dystrophy, and Hunter syndrome.

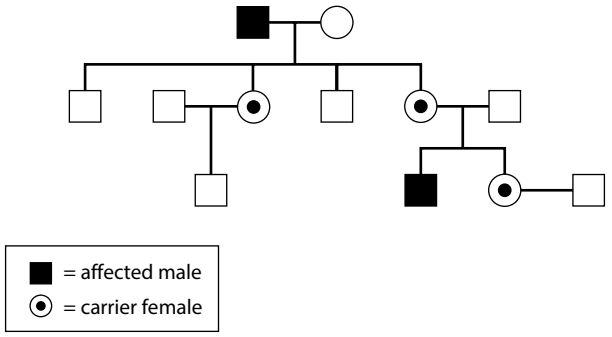

Figure 22.11 X-linked recessive inheritance.

Table 22.4 X-linked recessive disorders in neonatal surgical practice

System affected	Condition
Neurological	Hydrocephalus with aqueduct stenosis (some cases)
Hematological	Hemophilia
Skeletal	Amelogenesis imperfecta
Endocrine	Androgen insensitivity syndrome
Metabolic	Adrenoleukodystrophy

The daughters of a man with an X-linked recessive condition are all obligate carriers. The sons of a man with an X-linked condition are all normal, as they inherit his Y chromosome and not his X chromosome. When a woman is a carrier of an X-linked condition, each of her sons has a 50:50 chance of being affected, and each of her daughters has a 50:50 chance of being a carrier. There can be a relatively high mutation rate for some X-linked recessive conditions, and affected boys may not have any family history of the condition. About one-third of cases of boys with Duchenne muscular dystrophy occur as a result of new mutations. Prenatal diagnosis is available for a wide range of X-linked recessive diseases. The more common X-linked disorders in neonatal practice are shown in Table 22.4.

Polygenic inheritance

Many congenital conditions do not have a clear mode of inheritance and can be classed as polygenic or oligogenic, where a disease may arise as a result of the effects of several genes. A good example is cleft lip and palate, which usually occurs in the absence of a family history. However, monozygotic twins have a high concordance for cleft palate, suggesting a genetic influence. A similar model applies to the genetics of neural tube defects, which arise as a result of the combination of several environmental and genetic factors.

Other forms of inheritance

There are also much rarer forms of inheritance, including X-linked dominant. In X-linked dominant conditions, females may also be affected, despite having a second

normal X chromosome. These conditions can be hard to distinguish from autosomal dominant, except that females will be more mildly affected, and there is no male-to-male transmission. An example of an X-linked dominant condition is hypophosphatemic rickets.

Mitochondrially inherited diseases show a very unusual pattern of inheritance. Most of the proteins in the mitochondria are encoded for by nuclear genes, but the mitochondria also contain their own small genome of 18 kb, with many copies per cell. The mitochondrial genome replicates independently and far more frequently than the nuclear genome. Several important mitochondrial proteins are encoded by the mitochondrial genome. Mitochondria are only inherited via oocytes and not sperm. Therefore, where a gene alteration is in the mitochondrial genome, it will pass exclusively down the female line, but both males and females can be affected. The children of an affected male will not inherit his mitochondrial gene alteration. Children with mitochondrial disorders can present with many varied symptoms, including myoclonic seizures, acute acidoses, muscle weakness, deafness, or diabetes. A number of point mutations and deletions in the mitochondrial genome have been described in patients with a wide variety of conditions, including MELAS (myoclonic epilepsy with lactic acidosis and stroke-like episodes) or MERRF (myoclonic epilepsy with ragged red fibers on muscle biopsy). To complicate matters further, Leber's hereditary ophthalmopathy is a mitochondrially inherited condition, with a characteristic mitochondrial mutation, but the expression appears to have an X-linked recessive influence.

Some conditions show a phenomenon known as genetic imprinting. An imprinted gene has been marked during meiosis to indicate the parent from which it comes. For some genes, it appears to be important not only to inherit two copies of that gene but also to inherit one from each parent. Some genes may be silenced, depending upon which parent has passed on that gene. A good example is the presence of a small deletion of chromosome 15q, which has a different effect, depending upon which chromosome 15 is deleted. If the deletion occurs on the chromosome inherited from a child's normal father, the child will develop Prader–Willi syndrome. If the deletion occurs on the chromosome inherited from a child's normal mother, the child will develop a completely different clinical condition, Angelman's syndrome. The genes in this area of chromosome 15 are therefore imprinted. In addition, if a child has two maternal copies of chromosome 15 (maternal disomy), but no paternal copy, he or she will also develop Prader–Willi syndrome. Other conditions that show imprinting effects include Russell–Silver syndrome, Beckwith–Wiedemann syndrome, and the rare condition of transient neonatal diabetes mellitus.

An unusual molecular mechanism for genetic disease is that of inherited unstable triplet repeat expansions. In one of these genes, an unaffected person has a stable number of a repetitive element of three bases of DNA (for example, 20 copies of a CAG repeat) in a particular gene. In that case, the gene functions normally and the children of that person have the same number of repeats in their gene. An affected person has an increased number of repeats (say, 100 copies) in that gene, and the affected children of that person have more serious disease, with perhaps 200 repeats in the gene. Increasing numbers of repeats can result in a nonfunctional protein product or can lead to toxic accumulation of mRNA in the cells depending on the location of the triplet repeat and on the gene in question. The molecular genetic findings appear to be the genetic correlate of the phenomenon of anticipation, where a condition appears to worsen from generation to generation. The most extreme example is that of congenital myotonic dystrophy, where a minimally affected mother can have a profoundly affected infant. In this case, there is a small repeat expansion of, say, 150 repeats in the mother, increasing to many hundreds of repeats in her affected infant.

This molecular mechanism is responsible for Fragile X syndrome, Huntington's disease, Friedreich's ataxia, several forms of spinocerebellar ataxia, and probably several other conditions.

MOLECULAR GENETIC ANALYSIS FOR SINGLE-GENE DISORDERS

Genetic technology is moving at a remarkably rapid rate and becoming increasingly affordable in line with Moore's law. In the case of a well-known and easily recognizable monogenic disorder, targeted gene analysis using Sanger sequencing and multiplex ligation-dependent probe amplication (MLPA) will detect the majority of responsible pathogenic genetic variants, for example, analysis of the RB1 gene in a child with a unilateral retinoblastoma. However, other disorders require more specialist testing because of the nature of the genetic variants responsible for the condition. For example, neurofibromatosis type I is generally diagnosed on a clinical basis; but if molecular diagnosis is required, DNA analysis by Sanger sequencing and MLPA will only detect 70% of mutations. These types of analyses examine the coding regions of the NF1 gene, while a number of NF1 mutations lie in the introns between the coding exons. Analysis of these regions by RNA sequencing can increase the detection rate.

Other disorders may have a recognizable clinical phenotype but may be genetically heterogeneous. For example, Noonan syndrome is most commonly caused by mutations in PTPN11, but may also be caused by mutations in SOS1, RAF1, and RIT1, among others. In such situations, it may be necessary to undertake sequencing of a number of genes. This can now be achieved by using next-generation sequencing, whereby a "panel" of multiple genes is analyzed simultaneously. This strategy has a number of advantages including faster turnaround time and technical ease. However, such an approach runs the risk of detection of VUS in more than one gene. In such a case, a genetic alteration may be detected that is not directly associated with the clinical phenotype. This can make interpretation extremely challenging. Hundreds of genes may be interrogated simultaneously using this technology, but the most prudent approach is to undertake only targeted analysis of those genes known to

be associated with the clinical picture. A targeted approach limits the number of "incidental" findings of variants that may not be of clinical consequence, but that trigger significant workload in trying to delineate significance.

Genomic technology has developed to the stage whereby all coding regions of all known genes may be scrutinized contemporaneously, in the form of whole exome sequencing. Furthermore, all noncoding as well as coding regions may be sequenced as part of whole genome sequencing. Whole exome sequencing on average will detect 40,000–60,000 variants. Significant bioinformatics knowledge is then required to "filter" these variants to include only genes of interest. The interpretation of this type of data is highly dependent on the criteria used in filtering the available information, and therefore, close scrutiny of the phenotype and the pattern of inheritance in the family is required to produce meaningful and valid results.

Other laboratory tests for single-gene disorders have been available for a considerable amount of time. Hemoglobin electrophoresis for sickle cell anemia and thalassemia, and enzyme assays for Tay–Sachs' disease are very effective in resolving clinical issues in individual families. However, an increasing number of specific DNA-based tests can now be used in diagnosis and prediction of single-gene disorders.

The two major techniques used in molecular genetic analysis are the polymerase chain reaction (PCR) and Southern blotting techniques. PCR is a technique that allows amplification of a specific genetic region in large quantities from a small amount of DNA template (Figure 22.12). The DNA sequence of the region to be amplified must be known, so that synthetic pieces of single-stranded DNA (oligonucleotide primers) corresponding to the region can be designed and manufactured. The oligonucleotide primers are added in great excess to the DNA template, along with a thermostable DNA polymerase, and free nucleotides (A,C,T,G). The mixture is heated up to cause the two strands of template DNA to separate, and then cooled. As the DNA cools, the oligonucleotides bind to the template sequence and are extended by the polymerase. A new copy of the template DNA is thus produced. The cycle is repeated 30–40 times, with an exponential increase in the amount of the target sequence.

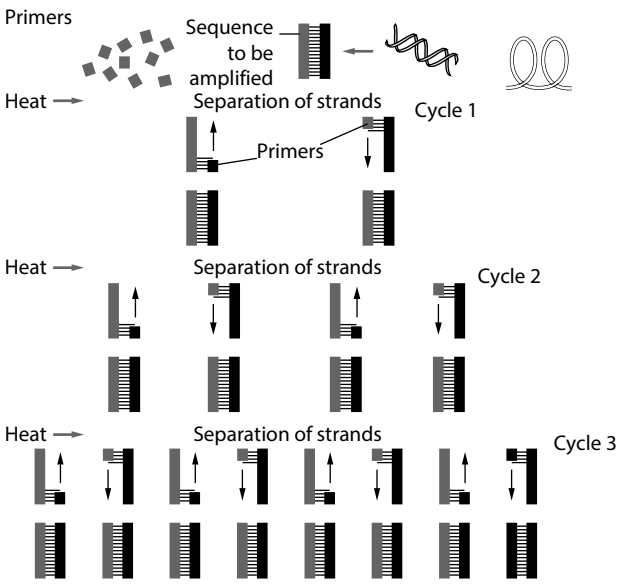

Figure 22.12 Polymerase chain reaction.

DNA generated by PCR can be used in many different ways to detect an abnormality in the sequence. If the test is aimed at detecting a known sequence abnormally, such as the common 3 base pair deletion on the cystic fibrosis gene Phe508del, the PCR product can be analyzed using mutation-specific oligonucleotide primers, or a DNA restriction enzyme test. If the search is for an unknown DNA mutation, such as those seen in hereditary breast and ovarian cancer, then many pieces of DNA generated by PCR from the patient can have their sequence analyzed using a semiautomated DNA analyzer.

Southern blotting is a more protracted procedure involving the digestion of a relatively large amount of DNA by a restriction enzyme. The digested DNA is then electrophoresed through an agarose gel, giving a smear of DNA of different sizes. The DNA is then transferred (blotted) and fixed to a membrane. The fixed DNA is then hybridized to a labelled DNA probe specific for the gene to be analyzed, and the specific sizes of DNA to which the probe binds allow determination of the "genotype" (Figure 22.13). This test is often superseded by PCR technology.

There are different degrees to which molecular genetic tests can contribute to clinical diagnosis. Some specific molecular genetic tests can be used to detect a known pathogenic DNA mutation and give a diagnosis, even without any knowledge of the patient's clinical status. For instance, the PCR detection of the Phe508del deletion in both copies of a person's cystic fibrosis (CFTR) gene immediately gives a diagnosis of cystic fibrosis. Such direct mutation tests are possible where the gene responsible for a condition has been isolated, and specific pathogenic mutations have been identified. Similarly, a PCR test detects a deletion of exons 7 and 8 in both alleles of a gene called SMN on chromosome 5q in almost all children with spinal muscular atrophy. Southern blot analysis of DNA from infants with congenital myotonic dystrophy shows a very large expansion in a triplet repeat DNA sequence in the myotonin kinase gene on chromosome 19, as described earlier under "Other Forms of Inheritance."

In other cases, molecular genetic diagnosis can point toward a diagnosis without confirming it. For instance, the presence of a single Phe508del CFTR gene mutation in a child with a history suggestive of cystic fibrosis increases the likelihood of the child being affected.

In some cases, where either a gene is not known or very few gene mutations have been identified in a known gene, gene tracking studies can be performed in a family to predict whether a person in that family is affected. This is known as linkage analysis. Such a study requires careful clinical examination of several family members to establish whether they are affected or unaffected. Where their clinical status is clear, DNA samples are then obtained.

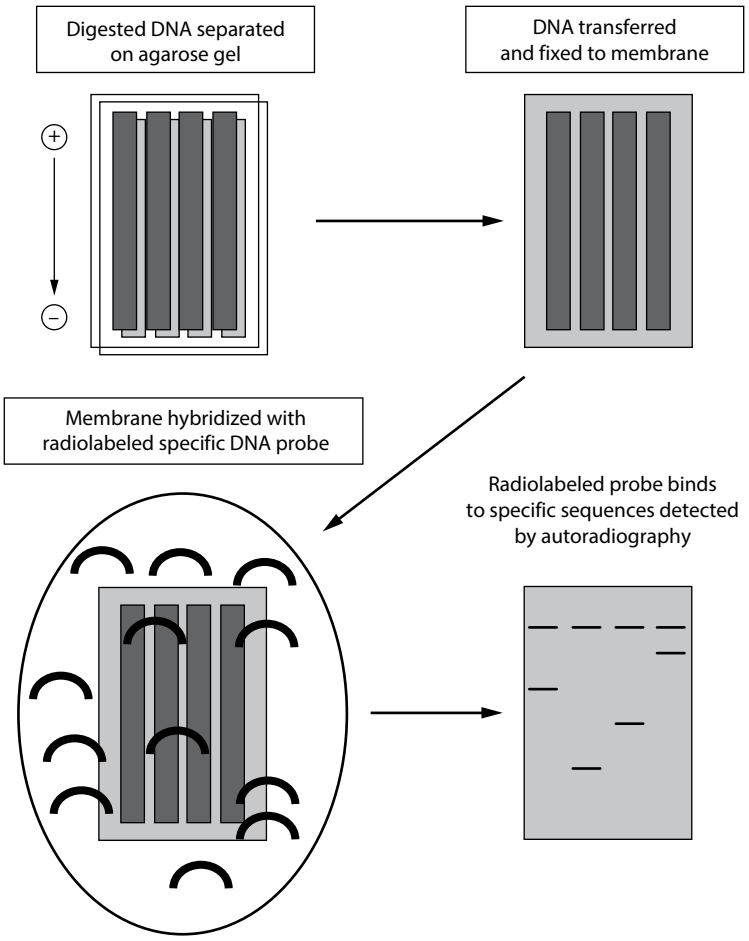

Figure 22.13 Southern blotting and hybridization.

Gene tracking analysis in the family uses the property of normal variation in a gene between different people. Some genetic areas show wide variation between individuals, and a DNA marker from such an area, which can detect many variations, is described as being polymorphic. Each variant of a polymorphic marker is known as an allele. There are now thousands of polymorphic markers covering most of the human genome, and such markers can be found very close to most known genes. There are several types of polymorphic DNA markers, including markers characterized by different numbers of specific DNA-cutting enzymes recognition sites or restriction fragment length polymorphisms (RFLPs). Other markers detect the variation in the number of anonymous elements of repetitive DNA and are called microsatellites or minisatellites.

If the two alleles of a polymorphic marker can be distinguished to discriminate between the two copies of that particular chromosome from where the marker comes, then the marker is informative in that individual. Where a gene location is known but the actual gene has yet to be found, the alleles of informative markers that lie on either side of the gene will be inherited along with each copy of the gene in question. This can be used to predict a child's clinical status.

If one set of alleles is found in the affected members of the family, but not in those unaffected, then the presence or absence of these alleles in the at-risk individual can be used to predict their chances of being affected. An example of linkage analysis for an autosomal recessive disorder is shown in Figure 22.14. This form of linkage analysis is often used in families with X-linked recessive conditions such as Duchenne muscular dystrophy to

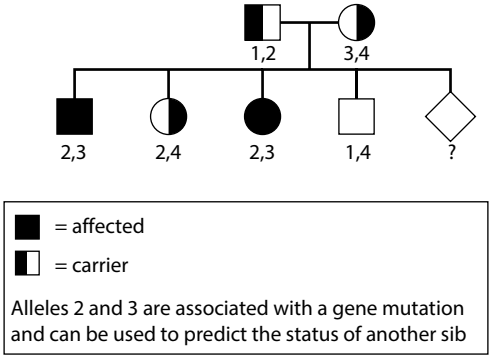

Figure 22.14 Linkage analysis in an autosomal recessive disorder using an intragenic polymorphic marker.

predict whether a woman is a carrier. Such linkage analysis can also be used in prenatal diagnosis.

Of its nature, linkage analysis is more prone to error than direct mutation testing. This can be due to difficulties in assessing a person's clinical status, and because of the possibility of recombination between the polymorphic markers. However, with the rapid advances in molecular genetics, many more mutations are being found in many different genes, and linkage analysis is often superseded by direct mutation testing.

CLINICAL GENETIC APPROACH TO DIAGNOSIS OF MALFORMATION SYNDROMES

Definitions

One child in 40 (2.5%) is born with a significant congenital anomaly, and 20%–25% of perinatal and childhood mortality is accounted for by congenital anomalies. Only a small number of these anomalies will occur as part of a specific genetic syndrome. A list of common congenital anomalies and approximate birth incidence is shown in Table 22.5.

Awareness of the possibility of a genetic or syndromal association for anomalies is very important for management of the patient and for advising the whole family. A distinction has also to be drawn between several different forms of abnormality, with appropriate definitions.

Table 22.5 Examples of major congenital anomalies

Type	Birth incidence (per 1000 births)
Cardiovascular	10
Ventricular septal defect	2.5
Atrial septal defect	1
Patent ductus arteriosus	1
Fallot's tetralogy	1
Central nervous system	10
Anencephaly	1
Hydrocephalus	1
Microcephaly	1
Lumbosacral spina bifida	2
Gastrointestinal	4
Cleft lip/palate	1.5
Diaphragmatic hernia	0.5
Esophageal atresia	0.3
Imperforate anus	0.2
Limb	2
Transverse amputation	0.2
Urogenital	4
Bilateral renal agenesis	2
Polycystic kidneys (infantile)	0.02
Bladder extrophy	0.03

A *disruption* can be defined as an anomaly that is caused by an interference in the structure of a normally developing organ. A good example would be the digital constrictions and amputations caused by amniotic bands.

A *deformation* can be defined as an anomaly that is caused by an external interference in the structure of a normally developing organ. An example would be talipes equinovarus caused by chronic oligohydramnios, perhaps from an amniotic leak.

A *malformation* can be defined as an anomaly that is caused by an intrinsic failure in the normal development of an organ. Common examples would be congenital heart disease, cleft lip and palate, and neural tube defects.

A *dysplasia* is an abnormal organization of cells in a tissue, often specific to a particular tissue. For example, achondroplasia is a skeletal dysplasia caused by a mutation in the FGFR3 gene. Most dysplasias are single-gene disorders.

A *sequence* can be defined as a group of anomalies that arise due to one single event. An example would be Potter's sequence. Potter's sequence (Figure 22.15) is the group of anomalies consisting of pulmonary hypoplasia, oligohydramnios, talipes, cleft palate, and hypertelorism. All of these anomalies arise as a result of the failure of urine production in the fetus. The cause of Potter's syndrome and failure of urine production could be posterior urethral valves, dysplastic or cystic kidneys, or renal agenesis, all of which can have genetic, nongenetic, or chromosomal origins. Pierre Robin sequence is the grouping of cleft palate, micrognathia, and glossoptosis, which can have at least 30 different causes. A sequence therefore does not have a specific cause or inheritance pattern.

An *association* can be defined as a clustering of anomalies, which is not a sequence, and which occurs more frequently than by chance, but has no prior assumption about causation. A good example is the association of VATER (vertebral anomalies, anal abnormalities, tracheoesophageal fistula, and radial or renal anomalies). There is no clear cause for VATER, although it can rarely occur in people with chromosome 22q11 microdeletions and can also rarely be mimicked by Fanconi's anemia.

A *syndrome* is a description of a group of symptoms and signs, and a pattern of anomalies, where there is often a known cause or an assumption about causation. The looser definition of "syndrome" to describe an anomaly should be avoided. The term can include chromosomal disorders such as Down syndrome or single-gene disorders such as van der Woude syndrome, which can cause cleft lip and palate with lower lip pits.

Approach to diagnosis

When a child is born with a congenital anomaly, several particular aspects of the history need to be explored. A good family history must be taken, with reference not only to a history of the same anomaly but other anomalies as well. A family history must include documentation of pregnancy losses, stillbirths and neonatal deaths. Any

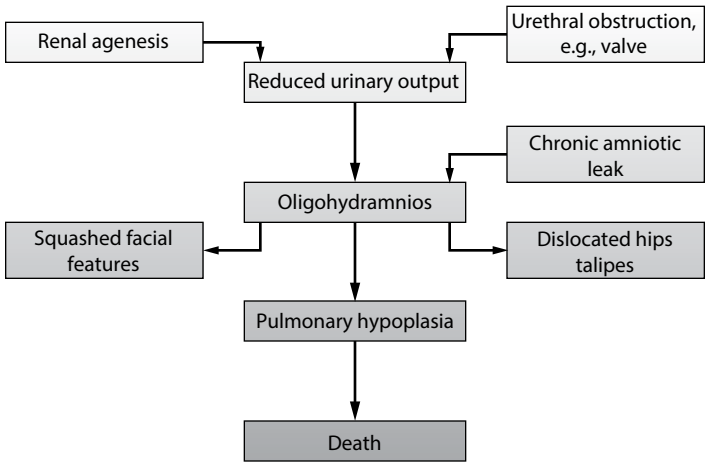

Figure 22.15 Potter's sequence.

history of potential teratogens in the pregnancy should be looked for, considering the likely embryological timing of the anomaly. Teratogens can include medications, recreational drugs, maternal diabetes, and prolonged maternal hyperthermia.

If a child has one congenital anomaly, a very careful examination should be carried out to check for any other more subtle abnormalities or for dysmorphic facial features, e.g., to check for hydrocephalus in an infant with a spinal meningomyelocele. If there is more than one malformation or significant dysmorphology, a chromosomal analysis should be requested, as chromosomal aneuploidy is a well-recognized cause of multiple malformations. A clinical genetic opinion should also be sought, as a clinical geneticist can often help greatly in achieving a diagnosis, as well as in counselling parents about the likelihood of recurrence of similar problems in other family members.

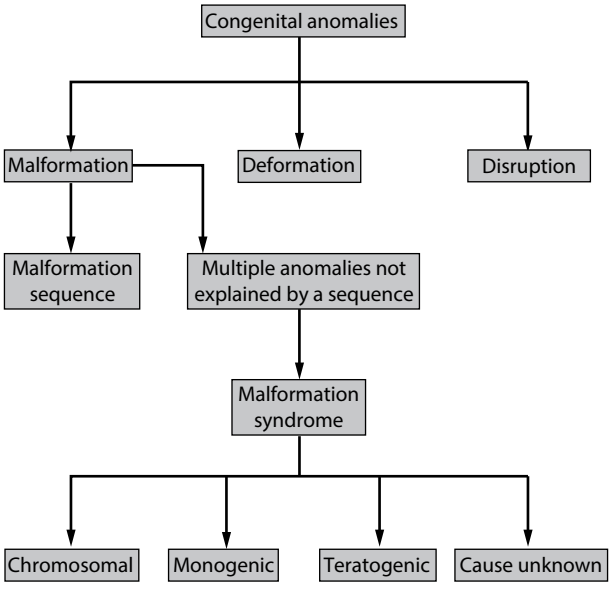

Figure 22.16 Diagnostic approach to congenital anomalies.

A diagnostic approach to congenital anomalies is outlined in Figure 22.16. Deformations and disruptions need to be excluded first. If the pattern of malformations fits into a well-described sequence, then a cause for that sequence should be sought. If the anomalies do not fit into a sequence, then a syndrome or association diagnosis should be attempted. If a syndrome diagnosis is achieved, it is important to remember that syndromes can be caused by chromosomal disorders, single-gene (monogenic) disorders, or environmental agents (teratogens).

The majority of congenital anomalies have a polygenic or multifactorial origin, and most are isolated (non-syndromal). The causes of congenital abnormalities are outlined in Table 22.6, and it is important to note that about 50% do not have a clear cause. Nonetheless, parents and families want an explanation as to the origin of their child's anomaly, and it is therefore worthwhile to pursue a diagnosis wherever possible.

This chapter is an introduction to the concepts and principles of genetics in neonatal surgical practice. It is not intended to be a comprehensive review of syndromes. Further information can be obtained from the bibliography and many Internet sources.

Table 22.6 Causes of congenital anomalies

Type	Relative frequency
Genetic	
Chromosomal	6%
Single gene	7.5%
Multifactorial/polygenic	20%–30%
Environmental	
Drugs, infections, maternal illness	5%–10%
Unknown	50%
Total	100%

GLOSSARY

3′ distal end of a gene, as indicated by the bond at the third hydroxyl group of the deoxyribose sugar.

5′ proximal end of a gene, as indicated by the bond at the third hydroxyl group of the deoxyribose sugar.

acrocentric a chromosome with effectively only a long arm—chromosomes 13, 14, 15, 21, and 22.

allele a genetic variation of a gene or DNA marker.

aneuploidy an excess or deficiency of chromosomal material.

anticodon an element of transfer RNA that binds a specific amino acid.

autosomal dominant inheritance pattern characterized by transmission through several generations, male-to-male transmission, and a 50:50 risk to the children of any affected person.

autosomal recessive inheritance pattern characterized by several affected members of the same generation, with carrier parents and a 1:4 recurrence risk where both parents are carriers.

base pair unit of double-stranded DNA.

centromere element of chromosome involved in chromosome replication, found as a constriction in the chromosome.

chromatid condensed chromosome found just before mitosis.

codon three base pair element of DNA encoding an amino acid.

diploid a complement of two copies of each chromosome per cell.

DNA marker a piece of DNA corresponding to a specific gene or chromosomal segment.

enhancers elements of DNA that are involved in increasing gene transcription.

exon a part of a gene that is transcribed into mRNA.

expression the way in which a gene fault manifests clinically.

FISH fluorescent in situ hybridization—a new and powerful technique for studying specific chromosomes or regions of chromosomes.

gamete a germ cell—sperm or oocyte.

genetic imprinting the marking of a gene according to which parent has passed the gene to its child.

haploid a complement of one copy of each chromosome per cell (as in sperm or oocyte).

haplotype a pattern of alleles of DNA markers representing one of the two copies of a chromosomal region.

histone a DNA-binding protein important in chromosomal folding.

interphase phase of mitosis in which the chromosomes are very elongated.

intron the part of a gene between the exons that is not transcribed into mRNA.

isochromosome an abnormal chromosome made up of two long or two short arms of a normal chromosome.

karyotype an analysis of the chromosome complement of a cell type.

linkage analysis the use of polymorphic DNA markers to perform gene tracking studies within a family.

meiosis the process of cell division to give haploid germ cells.

metaphase phase of mitosis in which the chromosomes are very condensed and easier to analyze.

microsatellite marker a DNA marker that detects variation in number of an anonymous small repetitive element of DNA.

minisatellite marker a DNA marker that detects variation in number of an anonymous medium repetitive element of DNA.

mitosis the normal process of cell division to give two diploid copies of a cell.

nondisjunction a failure of meiosis, giving two copies of a chromosome in one gamete, and no copy of a chromosome in the other gamete.

nucleosome the combination of a histone and its bound DNA.

oligonucleotide primers small lengths of synthetic single-stranded DNA of a specific sequence.

paracentric inversion a rearrangement of chromosomal material within one arm of a chromosome.

PCR polymerase chain reaction—a method of generating large amounts of specific DNA from a small amount of target sequence.

penetrance the number of people known to carry a gene mutation who manifest the condition.

pericentric inversion a rearrangement of chromosomal material around the centromere of a chromosome.

promoter element of a gene that is necessary to activate gene transcription.

prophase phase of the cell cycle where condensation of the chromosomes occurs, just before metaphase.

reciprocal translocation exchange of chromosomal segments between different chromosomes.

restriction enzyme an enzyme that cuts double-stranded DNA at a specific unique short DNA sequence.

restriction fragment length polymorphism a genetic variation between two copies of the same gene, where one gene may have one copy of a restriction enzyme recognition site, and the other has two copies. This variation can be detected using PCR or Southern blotting.

ribosome area of the cell where mRNA is converted into protein.

ring chromosome an abnormal chromosome in which the tips of the long and short arms have fused.

robertsonian translocation a fusion of two acrocentric chromosomes.

southern blotting a process of immobilizing DNA to nylon membrane for genetic analysis.

suppressor a DNA element that reduces the expression of a gene.

telophase the last phase of mitosis.

telomere the end of a chromosome.

transcription the process of converting DNA into mRNA.

translation the production of protein from a DNA sequence.

triploidy three of each chromosome, i.e., 69 chromosomes in man.

trisomy one extra chromosome, i.e., 47 chromosomes in man.

X-linked recessive inheritance characterized by affected males in several generations, and by female carriers.

23

Ethical considerations in newborn surgery

DONNA A. CANIANO AND JACQUELINE J. GLOVER

INTRODUCTION

In the course of routine practice, a pediatric surgeon often encounters clinical situations involving ethical choices, such as the following:

1. Counseling the parents of an extremely premature infant who is unstable following peritoneal drainage for perforated necrotizing enterocolitis
2. Providing prenatal consultation to a pregnant woman and her partner whose fetus has a high-risk congenital diaphragmatic hernia (CDH)
3. Deciding whether to participate in a prospective clinical trial for management of gastroschisis

Through case examples, this chapter provides the pediatric surgeon with an ethical framework to utilize in clinical practice when decision making may contain conflict with parental wishes as in the first case, risks and uncertainty (maternal and fetal) represented in the second instance, and the exercise of professional duties in the third instance.

The authors propose a set of guidelines and an organized process of establishing all relevant information, including what is known about the infant's medical and surgical condition and the relevant cultural and religious values of the parents. The totality of this information will come to bear on application of the *best-interests* ethical standard together with respectful acknowledgement of the role of culture in achieving a decision acceptable to the parents and the pediatric surgeon.

CASE STUDY 23.1

MS is a 21-day-old infant born at 25 weeks' gestation, weighing 575 g. He was stable on 50% oxygen and minimal ventilatory settings. He was on continuous feedings using a premature formula. At 21 days of age, the infant developed acute abdominal distention, intolerance to feedings, and bloody stools. Urgent consultation with the pediatric surgeon was requested. A radiograph showed diffuse pneumatosis. He was mottled, acidotic, and hypotensive. His laboratory values showed a white blood cell count of 2000, hemoglobin of 7 mg%, and a platelet count of 6000. He received packed red cells and platelets. Blood cultures were drawn, and he was started on triple antibiotics. The parents agreed to bedside peritoneal drainage. After 12 hours, MS remained clinically unstable, with worsening respiratory status. Laparotomy was advised by the pediatric surgeon, and the parents refused the operation.

MS's parents are from Nigeria and are in the United States on student visas. They have two other healthy children, aged 3 and 5, and plan to return to their native country in 3 months. The parents visit daily and are concerned about their son. Both the father and mother speak English. They ask appropriate questions and seem to understand their son's medical condition, prognosis, and alternatives for treatment. They desire that their son live but are strongly opposed to

TPN, especially since this technology is not available in their small city in Nigeria.

They acknowledge that MS is gravely ill and are accepting of his probable death. They say that they agreed to the use of all the previous medical technology because they thought it would save their son's life. But a life dependent on medical technology is too burdensome. They were expecting that their son would be able to live normally once he got out of the hospital. The parents explain that they have a strong faith in God; God will decide if their son lives or dies, and they will accept whatever happens. They believe that it is not in their power to alter God's will by the continued use of technology to support a life "that was not meant to be" and that if the boy is not able to eat like a normal infant, then it is better that he go to God. They have clearly stated their intention to return to Nigeria, where life-sustaining technology, such as total parenteral nutrition (TPN) and specialized nutritional formulas, are unavailable. In addition, they will not have access to pediatric specialists when they return to their native country, and worry about how they will secure medical and surgical care for an infant with a poorly functioning intestine and other chronic disabilities. What should the pediatric surgeon do? What is the best course of treatment for MS? What is the role of culture in this case, and how should it influence decision making?

GUIDELINES FOR ETHICAL DECISION MAKING

Ethical dilemmas most often arise when there is disagreement about a proposed course of treatment, what constitutes an acceptable quality of life, or what is in the best interest of the infant as perceived by the parents and by the pediatric surgeon. The authors have found the following questions to be useful in initiating an open and frank conversation with parents. The questions are intended as subject guides only; each pediatric surgeon should adapt the questions into his or her own style:

1. What is your understanding of your baby's current condition?
2. How has your baby's illness affected your family?
3. What is most important in the care of your baby?
4. What do you fear the most? What would you like to avoid?
5. What are your family's sources of strength and support?

Pediatric surgeons can help insure that their ethical judgments are reliable through the application of an organized process.[1] There are multiple versions available in the ethics literature, but they generally all contain the following components:

1. Identify the decision makers. Are the parents involved? Are there nonparental legal guardians? Do the parents have the capacity to make a decision? Who are the involved clinicians?
2. Gather the relevant medical facts. What is the diagnosis? What is the prognosis? Are additional tests necessary for further clarification? Is there necessary information to be gathered from other clinicians?
3. Solicit value data from all involved parties. Do conflicts exist among the values of the parents, other family members, and the physicians? Has the basis for the conflict been identified?
4. Define the available treatment options. With each option, what is the likelihood of cure or amelioration? What are the risks of an adverse effect? What is the minimum level of professionally acceptable treatment?
5. Evaluate possible treatment options and make a recommendation. Justify your choice according to the values of various parties.
6. Achieve a consensus resolution. Have all parties articulated their viewpoint? Would more factual information help to resolve any disputes? Would a mediator (ethics consultant, ethics committee, or other trusted third party) be helpful?

THE BEST-INTERESTS STANDARD APPLIED TO NEONATAL SURGERY

Since neonates and infants cannot make decisions about the appropriate use of technology based on their own personal values, the central ethical question is framed in pediatrics as, "What is in the best interests of this infant?" An answer requires a unique and complex ethical framework that combines a concern for who makes the decision and what decision is appropriate. In the United States, parents are presumed to be the appropriate decision makers for their infants.[1] Parents and pediatric surgeons must work together to make decisions that are in the best interests of infants.[2,3] The term *best interests* is meant to capture a balancing of the benefits and burdens to this infant of a particular intervention.[4]

In the mainstream medical culture in the United States, the term *best interests* was developed to focus attention on the need to assess the benefits and burdens of treatment for a particular infant from the infant's perspective. In an effort to be as objective as possible, only the direct pain and suffering associated with an infant's condition and/or proposed treatment was to be considered in conjunction with the benefit of continued life. The standard was proposed as a very strict one, regarding treatment as beneficial and in the infant's best interest unless the infant was dying, the treatment was medically contraindicated, or continued life would be worse for the infant than an early death. A central feature of this narrow understanding of best interests includes its child-centeredness, understood to mean the exclusion from consideration of the negative effects of an

impaired infant's life on other persons, including parents, siblings, and society.

A second key feature is its emphasis on the infant's concrete experience of burden in the form of pain and suffering. In addition to the difficulties associated with assessing the burdens experienced by an infant, a narrow best-interests standard cannot be applied to neonates and infants with neurological deficits so severe as to exclude the possibility of experience of any sort. Infants who are not responsive to outside stimuli, for example, cannot experience pain and therefore cannot be burdened in the same way as conscious infants.

Some ethicists have appropriately pointed out that absence of pain is not the only morally relevant feature.[5] A *relational-potential* standard is necessary to augment a best-interests standard. It is not morally obligatory to sustain life without any capacity for human relationship, even though life is not burdensome per se. Just as the presence of pain unable to be relieved can preclude the attainment of those basic human goods that make life worth living, so the absence of fundamental human capacity can render a life devoid of the same basic human goods.[6]

An expanded understanding of best interests must take into consideration several competing ethical values. One value is respect for family autonomy or self-determination. Families ought to have the freedom to make important choices about family welfare independent of others. It is not so much that families have a right to make important decisions for their infants as it is that families have the responsibility to make decisions and provide the necessary financial and other types of support. Families are an essential unit of care that is both valuable in itself and instrumentally valuable to meet the social goal of caring for children. Since families are presumed to love their children and desire to do what is best for them, they have a unique claim to the decision-making role. Also, families have to live with the consequences of the health care decisions that are made.[7]

In a very real sense, the families' interests are linked with the interests of the neonate or infant.[8] An attempt to starkly separate infant and family interests is artificial and diminishes rather than enhances an understanding of the infant's well-being. One can understand how the best-interests standard developed in the context of imperiled newborns, where there is great uncertainty and no one has a longstanding relationship with the infant. The objectivity sought is comprehensible only because the infant is a stranger to all. Yet even in the case of newborns, most authors agree that parents should be the primary decision makers.[9] If family interests were irrelevant, it would be difficult to make sense of such a presumption. Given this presumption in favor of parental decision making, and the fact that most infants are not strangers to their parents, a best-interests standard would be better understood to include a more comprehensive understanding of a child-centered decision, one made by a family whose daily lives involve the love and care of their infant.

Additionally, the search for the best interests of the infant apart from the family has several negative consequences. First of all, it can antagonize parents and turn all parties into adversaries. It can also cut off discussion and planning rather than improve it. Families may not feel free to discuss difficulties, and important needs may go unmet. Rather than search for some artificial "best" interest, all parties should acknowledge the complex goal of promoting the infant's well-being and the necessary interdependence of families in that endeavor. To exclude the family in a concept of child-centeredness is to reduce the infant to only a physiological organism and well-being to pathophysiological function.

Another value that is in tension with respect for family decision making is respect for professional integrity. Since *best interests* also contains an important focus on the uniquely medical interests of the infant, professional judgment plays an important role in describing and evaluating the benefits and burdens of health care interventions.[10] Pediatric surgeons have independent obligations to the infants who are their patients, to promote their well-being and protect them from harm. They have a professional obligation to promote life and quality of life, and to avoid such harms as killing, premature death, pain, and suffering. Yet even based on so-called medical facts, decisions are a complex amalgam of what the infant's alternative futures will be like, how likely it is that these futures can be gained, and what the infant has to endure to get there. An infant's present interests in being free from undue burdens must be weighed against all future interests.[11]

A third important value is that of justice as nondiscrimination.[12] How do we understand the interests of a child in himself or herself, independent of how others may value him or her? What does society owe its children as a matter of justice? Infants do not only belong to their families, but they also are members of their community. Communities have an obligation to protect the most vulnerable among them, especially if they are vulnerable to the neglect and abuse of their families. All infants deserve a certain level of health care, independent of what their families might choose for them.

The principle of justice also has another important component that is in direct conflict with the highly individualistic interpretation of best interests. In fact, a best-interests standard is an attempt to narrowly focus decisions on the patient himself or herself and to avoid greater issues of the just distribution of health care resources, but this is impossible. Families and communities struggle to consider what they owe each child, but also to consider what is fair for this child and all children together. Resources of time, effort, services, and money are limited within families and communities. Each must consider the impact of choices on the availability of resources for others. There is no doubt that questions of distributive justice are among the most difficult ethical issues that families, professionals, and communities must face. But they will never be resolved if they are simply ignored in the decision-making process. The authors agree

that allocation decisions are best made at levels other than at the bedside, as in the formulation of insurance plans and governmental policies. But these corporate allocation decisions will always have implications for bedside care and must not be ignored.

An expanded best-interests standard is an attempt to balance the benefits and burdens of a health care intervention according to the values of the parents, pediatric surgeons, and the larger society. It should be clear that the model described represents its application in the dominant medical culture in the United States. Firstly, other cultures and countries may have a different understanding of what constitutes family and necessarily include others besides parents. Perhaps others, such as family elders, are the persons designated as decision makers. Secondly, this particular model is based on western notions of the importance of informed consent and respect for the autonomy (self-determination) of the patient, and the family in the case of pediatrics. In other cultures and countries, families may not see their role as decision makers at all, only in terms of doing what the doctor orders. Also, other cultures and countries may emphasize other core values such as responsibility to the larger family and community rather than autonomy (self-determination). Finally, the model described presumes a certain access to technology that is primarily available in developed nations. A concern for quality of life is different in developed nations, where the issue may be the result of technology that is able to save life of diminished quality, as opposed to developing nations, where diminished quality of life may be primarily a consequence of inadequate access to basic health care services or the lack of advanced technology to support infants with chronic illness.

ROLE OF CULTURE IN DECISION MAKING

The ethical concept of best interests that has been articulated is largely dependent upon the authors' own experiences in the medical culture in the United States. In the case study of MS, we are compelled to value and respect cultural differences. Both his parents and the pediatric surgeon are struggling to fulfill their role-specific obligations to be good parents and a good physician. But they literally see their roles quite differently. It is culture that provides the lens for each of us to view the world. One definition of culture states,

> Culture is a set of guidelines (both explicit and implicit) which individuals inherit as members of a particular society, and which tells them how to view the world, how to experience it emotionally, and how to behave in it in relation to other people, to supernatural forces or gods, and to the natural environment. It also provides them with a way of transmitting symbols, language, art and ritual. To some extent, culture can be seen as an inherited "lens," through which individuals perceive and understand the world that they inhabit, and learn how to live within it. Growing up within any society is a form of enculturation, whereby the individual slowly acquires the cultural "lens" of that society. Without such a shared perception of the world, both the cohesion and the continuity of any human group would be impossible.[13]

It seems obvious from this definition that there is no way to talk about best interests from outside a cultural perspective. All of our discussion, then, is in some sense cross-cultural. The narrow explication of best interests represents the perspective of the United States, and perhaps predominantly the powerful status of its medical and legal culture.

A Nigerian anthropologist commenting on this case might point out that the United States has several unique cultural features. People in the United States tend to think that there is nothing worse than death—at least for a child or young person. Children are to be viewed as little adults—as individuals first and then only secondarily as members of a family or community, essentially independent of their families rather than dependent. Their right to grow up and to ultimately make their own choices is primary. US culture is very action oriented: when in doubt—act. The United Stated is also obsessed by the development and perceived power of technology. Technology and knowledge are primary goods.

But the central question is not really whether or not we have a cultural perspective, but whether we can judge some perspectives as better than others. This raises the difficult ethical question of cultural relativity. Cultural relativity refers to the following claims: (1) all moral judgments are relative to the culture in which they arise; (2) moral judgments across cultures are significantly different; and (3) there is no way to rank moral judgments across cultures.[14]

The well-respected physician–ethicist Edmund Pellegrino accepts that culture is essential in the context of medical and ethical decisions but that there are also features of human beings as human beings according to which we can judge among cultures.[15] It can be argued that there are some universal features that all cultures either should or would accept. An example would be that moral communities must allow democratic processes and cannot be oppressive.[16] The philosopher Sara Ruddick identifies three universal maternal interests that are applicable regardless of the particular form they take in a culture. These maternal interests include the following: (1) preservation, (2) growth, and (3) acceptability.[17] Other ethicists identify universal moral principles that underlie our commitments to be tolerant of cultural diversity.[18,19] Without some principle of respect for persons, for example, there would be no reason to prefer tolerance of cultural differences.

A cultural perspective is particularly important to ethical theorists, who support the inclusion of context and relationship in an ethical analysis, and to those of us working in clinical settings. As Carl Elliot writes,

> Ethical concepts are tied to a society's customs, manners, tradition, institutions—all of the concepts that structure and inform the ways in which a member of that society deals with the world. When we forget this, we are in danger of leaving this world of genuine moral experience for the world of moral fiction—a simplified, hypothetical creation less suited for practical difficulties than for intellectual convenience.[20]

The authors wish to support an ethical analysis that includes culture as an important feature but also acknowledges the role of the application of universal ethical principles. Like Pellegrino, the authors accept that there are some ethical principles that apply to all humans based on their humanity. Culture is necessary to understand what these principles mean and how they are applied with respect to each of the parties in the conflict. It is possible to be respectful of cultural differences and at the same time acknowledge that there are limits. What remains critical is the perceived degree of harm; some cultural practices may constitute violations of fundamental human rights. It is useful to return to case #1 and apply the process for ethical decision making with special attention to its cross-cultural features.

The family in this case clearly values their son's life and his quality of life. They also value the impact of this infant's life on their other children, the life of the family as a whole, and their plans to return to their native country. They accepted the initial use of technology in the care of their premature son, in the hope that it would deliver a "normal" infant, free of future dependence on medical technology. They are clear that for them, in a cultural and religious sense, a life dependent on TPN, specialized nutritional feedings, and the prospect of bowel transplantation is unacceptable.

For the pediatric surgeon and the other members of the health care team, the preservation of this infant's life is a goal, but the quality of his life is also a consideration. The laparotomy will allow the pediatric surgeon to assess the severity of the necrotizing enterocolitis (NEC), the amount of diseased bowel, and the prognosis for MS to have functional intestine without the need for prolonged TPN.

There are basically three options available in this situation. First, the pediatric surgeon can go forward with all the care that it takes to save this infant's life. This would include surgery, the use of TPN for as long as necessary, and all efforts to preserve the life of MS, including the possibility for bowel transplantation. This would more than likely include going to court to force the parents to consent to the operation and having a guardian appointed to make medical decisions for MS. This option could result in the permanent loss of parental rights and placement of the infant in the care of the state. In the second option, the pediatric surgeon performs the operation in the hope that there is sufficient residual bowel without the need for long-term TPN and bowel transplantation. If there is clearly not enough viable bowel, MS would be provided with comfort care and allowed to die. If there is sufficient residual bowel, care would proceed as appropriate. A difficulty arises if there is a questionable amount of bowel, and a trial of TPN would seem to be appropriate. The pediatric surgeon could resect the diseased bowel and proceed with a trial of TPN, discontinuing the use of TPN when it is clear that the bowel is not going to function normally. The third option is not to perform the operation. The infant could be maintained on current levels of support to see whether his bowel will heal on its own, or a comfort care plan could be initiated that would allow the infant to die sooner rather than prolonging the dying process.

The authors think that the first option is outside the range of moral justification and should not be recommended. The infant is critically ill with a disease that carries high rates of mortality and morbidity. Nontreatment for MS does not rise to the standard of medical neglect. The strongest argument for insisting on treatment rests on the claim that this infant is a member of the community, not only a member of his family. If families will not or cannot take proper care of their children, then we will step in to do so. But who is this "we"? If there is no such community support, or insofar as the broader community fails in this responsibility, then the community' s claim on the family's choice is diminished.

In this case, the Nigerian community (here or in Nigeria) does not make demands on the parents' choice. They do not see themselves as able, or obligated, to provide these services to MS. But in what sense is MS and his family a member of the US community? An argument can be made that they are community members by virtue of their residence. Yet they are planning to return to Nigeria. The argument that treatment must be forced because of community obligations seems diminished by their departure. We will not be around to provide the support we claim is necessary.

But will we provide the necessary support even if they stay? Is it possible for them to stay? Our community claims also seem diminished insofar as the family's student visa is not renewed, or access to health and social services is limited based on their foreign status. To claim that we are discharging our community obligations only by saving the child's life seems to greatly distort the notion of community.

But a final consideration needs to be mentioned. Couldn't we discharge our community responsibility by keeping the child here and placing him up for adoption? Then he certainly would become a full member of our community, and the concerns raised earlier would no longer apply. Such an action could clearly state that we believe the only appropriate parental choice is to try and save the infant's life. To choose anything else is to act as bad parents who should be replaced. Yet are they really bad parents? Such a judgment clearly raises serious concerns about cultural norms of parenting and fails to take culture into consideration. From the parents' cultural perspective, good parents would not choose surgery, and neither would good physicians. This is not the standard of care in Nigeria.

But how should culture figure into the deliberations of the pediatric surgeon? It obviously cannot simply be ignored

in a grand act of medical and parental imperialism. Also, we should not pay lip service to cultural perspectives, accepting the unusual and exotic only when it also fits into our own value framework. For example, this family could make the choice based on their cultural values only if there were a much higher mortality rate associated with the infant's condition. Finally, respect for different cultures cannot simply be some kind of ultimate trump. Automatically deferring to any choices based on cultural differences is to ignore the central values of our own culture. Ironically, it would be a violation of respect for cultural diversity in that our own cultural values are ignored. An attempt at negotiation and compromise is to be preferred.

The authors think that the pediatric surgeon should recommend surgery under the second scenario, saving the infant if possible, letting the infant die if appropriate, and negotiating a trial of TPN if necessary. But if this is not acceptable to the parents, the pediatric surgeon should respect the parents' decision not to have surgery and proceed with a plan of care aimed at keeping the infant comfortable until he either improves or dies. A decision by a pediatric surgeon to conscientiously withdraw from this patient's care out of concern for his or her own central values should be respected.

The second option is supported by the health care professionals' and the family's values. Surgery could save the infant's life, which all parties value, but it would do so under conditions of a quality of life that are acceptable to the family. Some health care professionals may have problems with this option if a trial of TPN is necessary. It is difficult to establish how long a trial of TPN should last. This difficult negotiation must consider what is medically feasible and also acceptable to the family. Also, many believe that there is a distinction between decisions not to start treatments (withholding) and decisions to stop treatments (withdrawing). Although this distinction is psychologically powerful, it is not ethically or legally valid in the United States.[21] If health care professionals and parents have sufficient justification based on the balance of benefits and burdens not to start a treatment, then they have the same justification to stop a treatment once begun. There is a hidden danger in maintaining this distinction between not starting and stopping medical and surgical treatments. Sometimes trials of therapy are not initiated when they are appropriate out of fear that the therapy cannot be stopped once it has begun.

Others argue that the provision of nutrition and hydration is different from other medical interventions, such as ventilators and dialysis, which are "extraordinary" and ethically can be withheld or withdrawn. According to this view, the provision of nutrition and hydration is ordinary and is always morally required. The attempt to classify categories of interventions independent of their application to the care of an individual patient is misguided. So-called ordinary treatments like antibiotics and the medical provision of hydration and nutrition can be disproportionally burdensome to certain infants and may be ethically forgone (withheld or withdrawn).[22,23] Many physicians and parents have particular values around the importance of feeding, regarding feeding tubes and TPN as morally equivalent to bottle or breast feeding an infant or to sharing a meal. Yet the provision of TPN is not readily comparable to feeding an infant or to a shared family meal. There are important differences. When hydration and nutrition are provided through medical means, they must be assessed according to the same principles used to evaluate any medical intervention. Decisions must be based on a careful evaluation of the proportionality of the possible benefits and burdens. For this family, TPN is burdensome not only because of the risk of frequent infections and the likelihood of progressive liver disease, but also because of what feeding through technology means in their culture, and the financial and social burdens to the entire family. The health care team in the United States cannot allocate this family's scarce resources for them, or for their country of origin.

CASE STUDY 23.2

A 35-year-old pregnant woman whose fetus was diagnosed at 18 weeks of gestation with a CDH is seen for prenatal consultation. She attends the visit with her husband, a self-employed electrician. They are the parents of a healthy 2-year-old girl. She works part-time as a nurse's aide at an assisted living facility and is active in their Christian church. They relate that they hope to have four children. Their male fetus has an isolated high-risk CDH with the liver up and an observed-over-expected lung-to-head circumference ratio <25%. The distraught couple relates that, although they have limited financial resources and no immediate family living close to them, they wish to do anything necessary to save their baby. What ethical obligations should guide the pediatric surgeon during the prenatal consultation? Should the pediatric surgeon inform the couple about a clinical trial of fetoscopic endoluminal tracheal occlusion (FETO) at a fetal treatment center nearly 1000 miles from their home?

The diagnosis of structural fetal anomalies by high-resolution ultrasonography at or around the 18th week of pregnancy is part of routine prenatal care in most developed countries. Identification of a fetal malformation typically prompts referral of the prospective parents to a pediatric surgeon for consultation about treatment and prognosis. However, the prenatal surgical consultation differs from the typical encounter between the pediatric surgeon and the parents of a neonate with a congenital anomaly, in which decisions center around operative intervention(s) for their already born infant. In the prenatal surgical consultation, there is an *expectation* of a future patient if the fetus is brought to term.[24] The unique role of the pediatric surgeon may be characterized as both an expert adviser and an expert counselor

to the prospective parents. Furthermore, the advent of fetal intervention for both life-threatening conditions (CHD) and serious, non-life-threatening conditions (myelomeningocele) has increased the complexity of the prenatal surgical consultation. No longer is the encounter between the pediatric surgeon and the prospective parents confined to an explanation of the malformation, postnatal treatment, prognosis, and expected quality of life. A discussion of all available prenatal interventions, including fetal surgery, should also be within the scope of the consultation.

Ethical guidelines for prenatal surgical consultation are rooted in the dominant field of genetic counseling, a field that developed in the late 1960s after the human chromosomes could be karyotyped and carrier status of inherited diseases, such as cystic fibrosis and sickle cell anemia, could be identified. Value neutrality emerged as the prevailing ethic for genetic counseling with objectivity for the counselor and promotion of autonomy for the patient/client.[25] Historically, genetic counselors strove to be nondirective and supportive in their approach, allowing the patient/client full latitude in decision making. However, the authors believe that value neutrality fails to encompass the entirety of the pediatric surgeon's professional moral obligation during the prenatal consultation. Prospective parents have an expectation that the pediatric surgeon will offer them expert advice about the next steps in management of the fetus. Failure to do so could be viewed as abdication of professional duty.

Another unique feature of the prenatal surgical consultation is the obligation of the pediatric surgeon to recognize the pregnant woman's right to make autonomous decisions about her pregnancy, including its continuation or termination. In our case study, the pregnant woman intends to continue the pregnancy, expressing the desire to do everything possible for a successful outcome. As noted by Chervenak and McCullough,[26] she thus confers on her fetus (although still previable) the moral status of a patient. Therefore, the pediatric surgeon assumes beneficence-based obligations for the fetal patient, but within the context of both beneficence and autonomy-based obligations to the pregnant woman. This tightly linked maternal–fetal ethical bond must be considered when the pregnant woman weighs the risks to her own health and well-being in undergoing a prenatal surgical intervention.

It must also be remembered that the prospective parents of a fetus with a significant congenital anomaly come to the prenatal surgical consultation with sorrow and grief, mourning the loss of an expected "perfect baby." As the esteemed physician Eric Cassel observed, "The relief of suffering is the fundamental goal of medicine."[27] While most individuals in western societies place high trust in advanced medical and surgical technology, the prospective parents also seek from the pediatric surgeon a palpable grasp of their suffering. During the prenatal surgical consultation, they want more than technical expertise; they hope for a sharing of empathy, and an understanding of their anxiety about the loss of the imagined future replaced by a new reality for their baby.

The ethical principle of justice should not be forgotten in the discussion of prenatal intervention. Justice requires all physicians to act in a fair and equitable manner in distributing medical care, and for the pediatric surgeon, in providing surgical care. In many countries including the United States, pregnant women who come from socially and financially disadvantaged backgrounds are at a higher likelihood of having limited access to and use of optimal prenatal services. There are limited data that describe the socioeconomic, racial, and cultural backgrounds of pregnant women who are referred for prenatal surgical consultation and for fetal treatment. We can assume that since fetal treatment centers in the United States and other developed countries are located in a few major metropolitan areas, pregnant women with limited financial resources and family/social support systems rarely have realistic options for prenatal intervention. As a society and as a community of pediatric surgeons, we should have both an interest and a concern that poverty, limited education, and other social barriers impact the future welfare of a fetus with a congenital malformation.

In addition to the usual surgical care for infants with CDH, the pediatric surgeon should inform the prospective parents about prenatal intervention with FETO, since their fetus may be a candidate for this procedure. The provision of this information to prospective parents raises additional ethical issues, since there are currently no agreed-upon guidelines among the pediatric surgical community for what constitutes requisite information during prenatal consultation for fetal CDH. Brown et al.[28] highlighted their concerns about the current lack of standardization in information for prenatal counseling for myelomeningocele, another fetal malformation for which prenatal repair may be an option. They cautioned that, in the absence of standardized counseling information, unintentional consultant bias may unduly influence the pregnant woman's ability to make fully informed decisions about fetal treatment. Bias may extend to the larger community in which the pediatric surgeon practices, including neonatal and perinatal specialists, local professional views toward referral away from the local children's hospital, and attitudes about the financial and psychological hardships associated with treatment at a remote fetal center. Furthermore, most prospective parents are unaware of the variation in the postnatal treatment of infants with prenatally diagnosed high-risk CDH (for example, ex utero intrapartum treatment (EXIT) to extracorporeal membrane oxygenation [ECMO], timing of operative repair, duration of ECMO therapy, etc.) among major pediatric centers in the United States.

The authors support an ethical framework that includes a standardized guideline for pediatric surgeons to use for counseling prospective parents with high-risk fetal CDH in which fetal intervention is an option. Information would include the full range of treatment options (prenatal and postnatal), expected outcomes, the local hospital's survival and morbidity statistics, long-term sequelae, and availability of clinical trials and treatment at a fetal center.

This information resource supports the pediatric surgeon's upholding both beneficence and autonomy-based ethical obligations. It also supports the ethical duty of justice and permits every pregnant woman/prospective parents, without regard to her/their socioeconomic, cultural, and ethnic background, to be in a better position to make informed decisions. In the present case, the authors support complete disclosure of all possible treatments, including referral to a fetal treatment center for possible prenatal intervention.

CASE STUDY 23.3

You have been invited to participate in a new prospective multicenter randomized clinical trial investigating the treatment of gastroschisis. Pediatric surgeons randomized to the experimental arm would be required to adhere to a standardized treatment protocol, including placement of a bedside silo, a certain type of abdominal wall closure, and a strict feeding schedule. Pediatric surgeons randomized to the control group would use their usual operative and feeding management. The primary outcomes of the study include hospital length of stay and age in days to achieve full enteral or breast feeding. The secondary outcomes are days on the ventilator, days of intravenous nutrition, number of days on antibiotics, bacteremia, and total hospital costs. Does the pediatric surgeon have an ethical obligation to participate in this research trial?

Nearly all significant advances in pediatric surgery have been achieved by the development of new operations and treatments or incremental modifications of existing procedures without professional oversight. In a field where congenital anomalies are relatively uncommon, each pediatric surgeon has been free to make individual choices about a preferred operative technique or management plan. Surgical innovation has historically occurred without significant prior investigation. A successful single patient outcome from a "new operative technique" often results in a limited patient series whose results are presented at a professional meeting. Whether or not the new technique achieves general utilization depends on several variables including the perceived need for a better technique by peers, reputation of the innovator, its ease of reproducibility, and results when performed by other surgeons. If the early results of the new technique or novel treatment are promising, it is typically followed by a plethora of presentations at professional meetings and peer-reviewed publications before it enters the realm of accepted practice. While surgical innovation is both necessary and noble, it may thwart the development of optimal treatments and operations and have the unintentional consequences of patient harm unless subjected to careful investigation.

Are there sufficient questions about the best management of an infant with gastroschisis that the pediatric surgeon should consider his or her ethical obligation to enter a clinical trial? Lusk et al.[29] have reported that there is considerable variability in the surgical and medical management of infants with gastroschisis among different pediatric centers and also among pediatric surgeons within the same institution. They also observed that there is no consensus among pediatric surgeons about the optimal management of infants with gastroschisis. In the current era of greater awareness for patient safety and health care costs, the authors propose that treatment variability without clear outcome benefits for infants with gastroschisis supports prospective clinical investigation.

The notion of equipoise describes the uncertainty about which treatment of surgical procedure results in the best outcome, given two or more alternatives.[30] At the personal level of a single pediatric surgeon, equipoise can be misunderstood because of thinking that a preferred surgical and/or treatment approach is superior to other methods, despite the lack of previous investigative support. Community and/or clinical equipoise provides a more inclusive view in which a state of uncertainty about optimal management of gastroschisis exists within the professional specialty of pediatric surgery regarding the merits of competing treatments and/or operations. The benefit of invoking community equipoise is that it permits an individual pediatric surgeon to retain strong preferences for his or her preferred management, and still agree that there is reasonable uncertainty within the profession about optimal treatment and/or operations.

Do the professional organizations in pediatric surgery expect their members to participate in clinical research trials? The principles of medical ethics in the bylaws of the American Pediatric Surgical Association list the following obligations of its members:

> Members shall strive to…acquire new medical and surgical knowledge through continuing practice in order to benefit patients…. Members shall recognize a responsibility to participate in activities benefiting the community.[31]

Nwomeh and Caniano[32] have pointed out that pediatric surgeons are uniquely advantaged to participate in prospective clinical trials because (1) the anatomic derangement and pathophysiology of uncomplicated gastroschisis is relatively uniform; (2) major children's hospitals with several pediatric surgeons on staff provide institutional support for clinical investigation; (3) community equipoise around optimal treatment for gastroschisis is achieved; (4) there is a history of major patient benefit derived from pediatric surgical participation in prospective clinical trials, such as the treatment of Wilms tumor and other solid malignancies; and (5) there is a very real possibility that prospective clinical trials with a substantial cohort of patients will uncover negative/suboptimal treatment consequences and unintended morbidities.

Ultimately, any research trial should satisfy certain ethical requirements as proposed by Emanuel and colleagues.[33]

1. Social or scientific value
2. Scientific validity
3. Fair subject selection
4. Favorable risk–benefit ratio
5. Independent review
6. Informed consent
7. Respect for potential and enrolled subjects

Since infants represent a special vulnerable group, additional procedures have been recommended to improve protection of pediatric research participants.[34] These include data and safety monitoring committees, a robust parental consent process, and decision monitoring that could verify the *informed* nature of the parental consent (that there was no coercion or undue incentive for participation).

Although not relevant to our study case, a final issue concerns the need for special protections for research in developing countries, as an increasing amount of research is, in fact, multinational. Emanuel and colleagues[35] have proposed an eighth principle—collaborative partnership—to be added to the seven requirements listed here. This principle emphasizes the need to develop partnerships among researchers, makers of health policies and communities. It recognizes the importance of respecting the community's values, culture, traditions, and social practices. And perhaps most importantly, this principle seeks to ensure that the recruited participants and communities receive benefits from the conduct and results of the research.

SUMMARY

In this chapter we have endeavored to address three realistic situations that involve ethical choices for the pediatric surgeon. In the first, case we highlighted the importance of using the best-interests standard for neonatal decision making, while respecting the place of the infant within his or her parental and familial cultural milieu. For the second case, we discussed the ethical obligations of beneficence, autonomy, and justice that the pediatric surgeon should maintain during prenatal consultation. Finally, we offered an ethical rationale for pediatric surgeons to participate in clinical research as a way to benefit their future infant patients.

Patient safety

IAIN YARDLEY

INTRODUCTION

During the 1990s, a growing realization emerged amongst the medical community that patients were being harmed during the course of their care. This came about through several highly influential studies[1,2] and reports.[3,4] The statistics presented were truly shocking: 1 in 10 patients experiences an adverse incident during a hospital stay[3]; deaths due to complications attributable to the provision of care are equivalent to an airliner crashing every week.[4] The potentially preventable ways in which patients come to harm are many and varied, from the most obvious and shocking, such as operating on the wrong body part or even the wrong patient[5] or accidentally giving an massive drug overdose[6] to less obvious and potentially overlooked events such as catheter-related infections and postoperative wound infections.[3,4]

What constitutes safe care is rather hard to define and can only really be categorized by the absence of dangerous care, as in the World Health Organization (WHO) definition: "the prevention of errors and adverse effects to patients associated with health care."[7] It is not possible to completely eliminate all occurrences that are included in the definition of an *adverse event*, for example, surgical site infections, but it is likely that their incidence can be reduced. Patient safety has therefore concentrated on minimizing and subsequently eliminating potentially avoidable harm.

Once it was acknowledged that healthcare was a hazardous undertaking, with significant risk of causing harm to those it was trying to help, the concept of *patient safety* grew, and the mainstream media, policy makers, and clinicians all took up the issue with a real sense of outrage and urgency. Efforts to reduce the risks encountered during patients' care were given the highest possible priority.[8] With little experience in healthcare of improving safety across a system, early workers in patient safety looked to other high-risk industries, most notably the aviation industry, with its enviable safety record for inspiration and advice on how healthcare could follow their lead in making care safer. Several concepts and ideas have been introduced to the healthcare setting following their successful implementation in other arenas, such as the use of checklists[9] and reporting and learning systems.[10] Since the 1990s, patient safety has developed into a specialty of its own with huge resources invested into it, its own terminology (Table 24.1), and scientific journals dedicated to its study.

A very early realization for those working to improve patient safety was that the traditional model in healthcare—the person approach, where individuals carried responsibility for their actions and behavior, so if something went wrong, someone was to blame—was flawed. It was recognized that uncaring or careless individuals were not (in the vast majority of cases) the cause of safety incidents. These incidents occurred due to flaws in the systems in which healthcare workers operated and patients were cared for.[11] Rather than attempting to change individuals' behavior, changing and strengthening the systems that staff work in is much more likely to lead to improvements in safety.

SYSTEM THINKING

This *systems approach* has been the philosophy underlying the vast majority of patient safety work. Highly influential in this approach is Reason's[12] "Swiss cheese model." In this model, the multiple layers of defense that an organization has are represented by slices of Swiss cheese. For example, when prescribing a drug in the neonatal unit, the layers of defense that are intended to ensure the baby receives the correct dose of the correct medication are as follows: the initial writing of the prescription by the doctor; the pharmacist in the unit checking the prescription; the nurse responsible for administering the drug checking the prescription and drawing up the medication; and the nurse and his or her colleague administering the drug to the patient. However, these layers of defense are not perfect. Like Swiss cheese, they contain holes, or *latent errors* that can allow *active errors* to pass through the system and reach the patient,

Table 24.1 Glossary of terms used in patient safety

Patient safety term	Definition
Patient safety incident	Any situation that causes, or has the potential to cause, a patient to experience an adverse outcome.
Adverse outcome	Any situation where the final result of an episode of healthcare is suboptimal.
Adverse event	Any event that leads to an undesirable outcome associated with healthcare. An adverse event does not necessarily have to be associated with an error. For example, surgical site infections can occur despite all appropriate measures to prevent them being in place.
Error	An action that leads to an undesirable outcome. Theses can be acts of commission, e.g., prescribing the wrong dose of an antibiotic leading to renal damage, or of omission, e.g., not prescribing antibiotic prophylaxis appropriately and increasing the risk of surgical site infection.
Latent error	An attribute of a system that makes an adverse event more likely, for example inadequate staffing levels leading to staff members being overworked and fatigued and more likely to make mistakes. These could be described as "accidents waiting to happen."
Active error	An incorrect action that occurs at the interface between the healthcare system and the patient whose effect is usually rapidly evident. Active errors are almost always associated with one or more latent errors.
Critical incident	An incident (usually undesirable) that is particularly significant. Studying critical incidents can help prevent future adverse events. This is the principle behind reporting and learning systems.
Reporting and learning system	A system enabling the study of incidents to learn lessons from them and implement measures to reduce the likelihood of their recurrence.
Root cause analysis	An incident investigation technique that aims to discover the factors that underlie the occurrence of an incident rather than focus on the actions of individuals.
Near miss	A patient safety incident that had the potential to lead to harm but did not, either through good fortune or due to the fact that it was identified before affecting the patient. Studying near misses can be as informative as studying incidents that lead to harm.
Never events	A list of patient safety incidents that are serious and preventable if adequate safety systems are in place. Never events related to surgical care are operating on the wrong patient or body part, inserting the wrong surgical implant, and leaving an item in a body cavity following surgery.
Sentinel event	A patient safety incident that is particularly egregious or serious and implies that the organization in which the event occurred has significant systemic failures. Never events are generally considered to be sentinel events.
Swiss cheese model	A conceptual model for safety. The basis of the model is that any organization will have layers of defense against harm, and any one of these layers can prevent harm from reaching the patient. However, all of these layers are imperfect and contain holes, like a Swiss cheese. Only when these holes align can harm penetrate the system's defenses and reach the patient.
Human approach	A way of approaching patient safety incidents that concentrates on the actions of individuals and tries to eliminate future incidents by changing behavior through training, reminders, or reprimands.
Systems approach	A way of approaching patient safety incidents that acknowledges that individual workers are fallible and will make mistakes. Prevention of harm is more likely to come about by improving the systems people work in to prevent or detect these mistakes before they cause harm than by trying to create perfect workers who never make mistakes.
Human factors	The area of study that applies to how individual workers interact with their environment. This approach has been hugely influential in the study of patient safety.
Safety culture	An organizational attribute where the hazardous nature of the organization's activities is acknowledged and safety takes a high priority at all levels of the organization.

causing harm. In the example of the drug prescription, the doctor might be distracted by an emergency in the labor ward while writing the prescription (a latent error) and write up 10 times the intended dose of the drug (the active error). That day, the ward pharmacist is off sick, and no cover is available, so the prescription is not checked before it is time to administer the drug (another latent error). The nurse drawing up the medication usually has a calculator to assist in checking drug doses, but the battery has run out, so it cannot be used (the third latent error). As he knows and trusts the doctor who wrote the prescription, he or she draws up the drug as prescribed without repeating the calculations used to derive the dose (an active error). The second nurse that she gets to check the drug is her junior colleague and does not like to challenge her work (the final latent error) and so countersigns the prescription without checking the quantities herself (an active error), and a fatal overdose is delivered to the neonate. Any one of the layers of defense could have recognized the error and prevented it from reaching the patient. It was only when several latent and active errors coincided that the holes in the cheese lined up, allowing the patient to be harmed (Figure 24.1).

The application of system thinking to patient safety relies on the acknowledgement that active errors will inevitably occur, through either omission or commission. Attempts to eliminate these errors by changing the behavior of individuals, for example, through education or reminders, are likely to fail. Instead, a systems approach looks to increase the number of ways in which an error can be detected (increasing the number of layers of cheese) and make these defenses as robust as possible (making the holes in the cheese smaller). In the example given, if a person approach to error were taken, the response to the event occurring would be to reprimand or discipline the doctor who wrote the prescription. However, the doctor did not write up a massive overdose because he did not know or had forgotten that this was incorrect. It was a mistake, so telling him not to do it again is unlikely to prevent a recurrence. A systems approach to prevent a similar error recognizes this and so would include many changes, including the following: employing extra doctors so that emergencies in the labor ward do not distract doctors working in the neonatal unit; developing cross-covering arrangements within the pharmacy department so that sick leave does not leave a clinical area uncovered; providing solar-powered calculators in all drug preparation areas; and developing team training for the nursing staff to flatten hierarchies and allow appropriate challenge even to senior colleagues when checking drugs.

There are many barriers to the implementation of system thinking based approaches to patient safety. Perhaps the most significant is the cultural change that is required for healthcare to move from its traditional stance of individual blame to a systems approach. Other impediments are that system-based approaches are more expensive in terms of time and resources both in the investigation required to determine the underlying causes of an incident and in the actions needed to reduce the risk of recurrence. In the example given, it would be far quicker, simpler, and cheaper to simply reprimand the doctor than implement the actions described.

SAFETY CONCERNS SPECIFIC TO SURGERY

Adverse events in surgery often appear starker, and consequently receive more attention, than other types of safety incident. This is due to a surgical procedure being a well-defined and discrete event, whereas other stages in a patient's care, such as establishing a correct diagnosis, occur at less

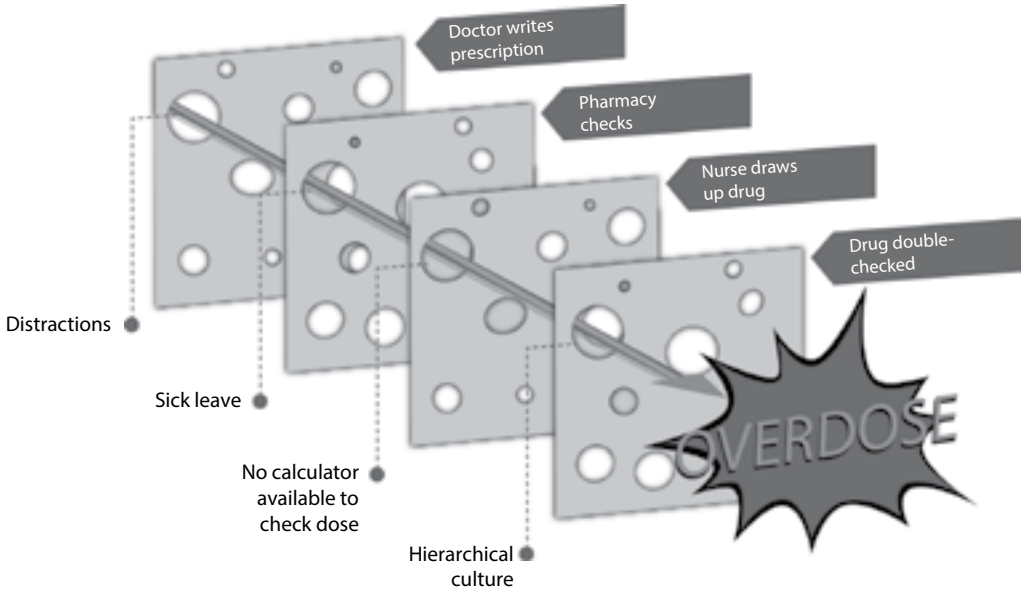

Figure 24.1 The "Swiss cheese model" of organizational defenses. (Adapted from Reason J., *Human Error*, Cambridge University Press, Cambridge, UK, 1990.)

distinct points in time. There are three surgery-specific incident types that have been termed *never events*. Never events are a group of safety events that are preventable using established safety procedures and so are considered inexcusable and should never happen. If they do happen, then it suggests there may be serious failings in the approach taken by the organization concerning patient safety.[13] The never events that relate specifically to surgical care are as follows: operating on the wrong patient or on the wrong body part, inserting the wrong implant, and leaving items inside the patient unintentionally following surgery.[14] Despite the term *never event*, these incidents still occur across healthcare settings and have shown little sign of decreasing in frequency.[15] Although it may seem hard to comprehend how such errors could occur with competent and conscientious medical staff on duty,[16] the systems in operation during surgical care are incredibly complex, and there are many opportunities for errors to occur, no matter how conscientious individual staff members are. For example, when performing a left inguinal herniotomy, the surgeon needs to make no fewer than eight mental steps after encountering the supine patient to fully transfer his or her understanding and concept of *left* to that of the patient's left groin and operate on the correct side.[17] An error in any one of these steps will potentially lead to operating on the incorrect side.

In addition to these clearly defined errors, there are many more subtle ways in which surgical patients can suffer harm during their care. These sources of harm can be preoperative, such as delays in diagnosis; intraoperative, such as allowing the patient's body temperature to drop below an acceptable limit; and during the postoperative period, such as developing surgical site infection. It is often impossible to identify one single cause of the adverse outcomes due to the complexity of the care provided and the multiplicity of factors affecting outcomes. No single distinct event, error, or omission will be responsible for an unexpected outcome, such as a surgical site infection. Rather, it is a combination of factors, including timely surgery, appropriate antibiotic prophylaxis, good temperature control intraoperatively, and so on, that is required to reduce the risk of infections.[18] Indeed, many adverse outcomes are not related to errors, of either omission or commission, and are unavoidable consequences of the patient's condition. Patient safety does not aim to eliminate adverse outcomes; rather, it aims to minimize them by eliminating those that are potentially preventable. For example, blood loss may be inevitable during surgery, so hemorrhage is not in itself necessarily due to an error. However, a failure to prepare for blood loss and not having adequate venous access for resuscitation or blood products for transfusion is a potentially preventable error.

Safety concerns specific to newborn surgery

The newborn surgical patient is susceptible to all of the same hazards as any other surgical patient, but in addition, these patients have unique attributes that increase their vulnerability to harm during their care.

SIZE

Newborn surgical patients are simply physically smaller than other surgical patients, sometimes extremely small.[19] This leads to increased risk from several sources. Firstly, decreasing the size of a body rapidly increases its surface area–to–volume ratio. In newborns, this means that they will lose heat far more rapidly than older patients and so are at risk of hypothermia and its attendant complications. Being small means newborns are more physically fragile than older patients and at risk of iatrogenic injury including fractures, particularly during transfer within or between healthcare facilities.[20] Physical fragility is also a source of risk when inserting tubes, as is common in the newborn surgical patient, for example, the danger of esophageal perforation with a nasogastric tube or bladder perforation with a urinary catheter.[21,22] Vascular access to deliver vital medications and fluids and to monitor the patient's condition is also more challenging in the newborn. Tiny, fragile veins make extravasation injuries a significant risk,[23] and the fine-bore catheters necessary for vascular access in the newborn make them more vulnerable to blockage and the need for replacement. A small circulating blood volume means that only minimal blood loss can lead to significant compromise of the neonatal circulation. Finally, when it comes to operating on newborns, their small size makes surgery more technically challenging and demanding, increasing the risk of complications such as wound breakdown and anastomotic leaks.[24]

ANATOMY

The anatomy of the newborn is not simply a smaller replica of the older child, as discussed elsewhere in this book. Several aspects of these anatomical differences create an increased risk when operating on the newborn. The liver and bladder are both relatively much larger than in older children, putting them in greater danger of iatrogenic injury during laparotomy or laparoscopy. The newborn liver also has a very tenuous capsule and friable parenchyma, which, coupled with an increased right heart pressure, makes liver injury and subsequent bleeding both more likely and harder to control than in the older child. As a baby completes the adjustment from the fetal to neonatal circulation, his or her cardiovascular system also presents specific risks to his or her surgical care. The foramen ovale and ductus arteriosus are commonly still patent, allowing shunting of blood from right to left, and hence, paradoxical emboli from the venous system can enter the arterial system and cause cerebral or other arterial infarcts. When combined with the patent umbilical vein, this can lead to major harm due to gas embolus during laparoscopy.[25]

IMMATURE ORGAN SYSTEMS

Many of a newborn's organ systems are still immature, especially for infants born prematurely; this makes their care

more challenging and hazardous in several ways.[19] Perhaps most obviously, a premature baby's lung is not fully developed, necessitating ventilatory support. This will need careful management alongside the management of coexisting surgical conditions. In some specific newborn surgical conditions, notably diaphragmatic hernia, specific measures need to be undertaken to prevent iatrogenic damage to the immature or underdeveloped lung.[26] A newborn baby's skin is more permeable than the older child's, making bacterial translocation and subsequent sepsis more likely; transepidermal water loss is also increased, allowing both water and heat to escape.[27] Newborn surgical patients will therefore need careful attention paid to skin care perioperatively to reduce the risk of harm. The newborn kidney is also immature and less able to concentrate urine, making fluid balance potentially more challenging. During the newborn period, there is an exchange of hemoglobin from fetal to adult type; this creates bilirubin as a by-product that can overwhelm the neonatal liver, causing jaundice. The management of jaundice is a routine part of neonatal practice, but it is vital that it is not overlooked due to distractions from any concurrent surgical issues.[28] Glucose handling is commonly impaired in the neonate and requires careful monitoring and treatment to prevent serious complications.[29] In the newborn surgical patient, the stress of a surgical procedure and the prolonged fasting that is common during his or her perioperative course make careful glucose monitoring even more critical to prevent harm. The newborn brain is also relatively immature, especially following premature birth. This can create risks to the patient both directly and indirectly. Direct risk comes from the fragility of the blood vessels in the brain and bleeding leading to intraventricular or periventricular hemorrhage and the potential for the subsequent development of cerebral palsy.[30] Careful management of blood pressure and circulation is therefore vital in the newborn surgical patient, particularly intraoperatively. Indirect risk arises from a baby's inability to communicate with caregivers. Babies cannot tell the surgeon what symptoms they have, making accurate diagnosis and timely treatment more challenging. They are also unable to confirm what procedure they are due to undergo, potentially increasing the risk of wrong-site surgery.

ACUITY OF PROBLEMS

Many newborn surgical conditions require urgent or emergent operative intervention, for example, gastroschisis and perforated necrotizing enterocolitis (NEC). Even with antenatal diagnosis of a surgical condition, the timing of delivery is often unpredictable, and babies can be born at any time of the day or night. Similarly, babies with NEC can deteriorate at any time of the day or night, precipitating the need for surgical intervention. This acuity of newborn surgical conditions can lead to the need to operate outside normal working hours. This creates fatigue in healthcare workers, which is known to degrade both technical performance and decision making.[31] Staff can also become isolated when working out of hours when assistance may be harder to obtain during challenging or unexpected procedures.

COMORBIDITY

Although some newborn surgical patients will have an isolated condition that requires surgical correction, many will have other associated issues, especially those born prematurely. Some of these were mentioned previously, such as lung disease of prematurity, but there are others such as concomitant congential cardiac lesions found with the VACTERL (vertebral, anorectal, cardiac, tracheo-esophageal, renal and limb) association or other midline anomalies such as exomphalos. All need careful and coordinated multidisciplinary management and are not uncommonly the major determinants of outcome for newborn surgical patients.[32]

HEALTHCARE SYSTEM LIMITATIONS

The design of healthcare systems is often not optimized for the care of newborn infants with surgical issues. This is largely due to the relative rarity of these conditions, with systems appropriately focused on more common conditions. Newborn surgical expertise is concentrated in specialist centers, necessitating transfer from the place of birth in undiagnosed conditions. This need for transfer can create risks due to delays in care as well as the physical risks involved in interfacility transport.[20] Patient identification systems used in hospital usually include the patient's name. The requirement in hospital systems for a given name to be recorded means that it is not uncommon for newborn patients to be referred to as "Baby" until they are named by their parents. This creates the risk of misidentification and potentially wrong patient surgery.[33] The low volume of surgery carried out in newborns means the market for equipment designed for this type of surgery is limited, so manufacturers (with a few notable exceptions) have not produced tools specifically designed for small patients. This has led to the use of surgical equipment designed for adults in newborns, which can create the risk of harm.[34]

MEASURES TO IMPROVE SAFETY

As mentioned earlier, patient safety is now a specialty in its own right with an ever-growing evidence base. Unfortunately, very little work on patient safety has been done in pediatric surgery and even less in newborn surgery specifically. This leaves pediatric surgeons reliant on lessons learned in other surgical disciplines. There have been many studies published that investigate the nature of safety incidents in surgery but rather fewer that describe successful means to reduce their occurrence. Key safety interventions that have been developed for surgery include checklists, incident reporting, and training in nontechnical skills.

Checklists

Checklists have been used for many years by pilots to ensure that important steps are taken in preparation for key points during a flight, for example, immediately before and after takeoff or landing. The hope was that they would

prove equally useful in ensuring that safety-critical steps were performed in healthcare.[35] The clearly defined event of performing surgery is an obvious moment at which a checklist could be deployed. Surgical checklists have taken several forms, the Joint Commission's Universal Protocol, introduced in 2003,[36] being one of the first to bring together standard safety steps into one document. In 2008, WHO's safe surgery checklist was launched as the centerpiece of the Safe Surgery Saves Lives project (Figure 24.2).[37] This project brought together international experts from the fields of surgery, anesthesia, and system safety to develop a means to improve the safety of surgical patients worldwide. Their work built on and expanded previous experience such as the Universal Protocol. The WHO surgical checklist is a 17-item checklist in three sections; before the induction of anesthesia, before commencing surgery, and before the patient leaves the operating room (Figure 24.2). A multicenter before-and-after trial of the use of the checklist in a variety of healthcare settings showed a dramatic reduction in surgical mortality and morbidity.[38] This reduction has been replicated in several studies of the checklist since the initial trial, including a randomized controlled trial.[39] A further expansion of the concept of checklists to cover the whole of a surgical patient's admission to the hospital has also been demonstrated to reduce surgical mortality and morbidity.[40] Away from surgery, another study demonstrated that by using a checklist when inserting central lines in a critical care unit catheter-related bloodstream infections could be almost eliminated.[41]

ADAPTING THE CHECKLIST FOR NEWBORN SURGERY

The WHO Guidelines for Safe Surgery that accompany the checklist encourage local adaption of the checklist to suit the circumstances (although not removing items, as they were all felt to be essential steps in performing safe surgery).[37] Useful adaptations when carrying out newborn surgery might include the following: ensuring adequate warming measures are in place as neonates are highly vulnerable to heat loss during surgery; creating the opportunity to review any relevant comorbidities, such as congenital cardiac lesions, that might affect surgery; checking that appropriate blood and blood products are available should they be needed rapidly during surgery; and ensuring that all intravenous lines are purged and flushed before leaving theatre to prevent later accidental administration of anesthetic agents.

The success of surgical checklists in early studies initially raised the hope that this would be a simple, quick, and cheap solution to many patient safety problems. However, replication of the results of these studies outside of clinical trials has been patchy, with limited uptake of the checklist[42] and improvements in outcome not necessarily related to the use of the checklist.[43] It appears from further study of both the WHO checklist and the central line checklist that complex social and cultural factors at play around the implementation of the checklists were at least as important as the checklist itself in improving safety.[44,45] It is common for staff members, particularly surgeons,[42,46] to resist the use of the checklist in their daily practice. Successfully embedding checklist use in a department's routine requires a significant cultural change and takes time, even years to achieve.[47] Central mandates on checklist use from politicians or policy makers are unlikely to lead to effective use of the checklist.[48,49] Longer-term approaches are needed that take a more holistic view of the checklist and the environment that it is used in. Checklist implementation programs that involve the whole operating team in training have been shown to be more successful at achieving checklist use and reducing mortality.[50]

Reporting and learning

Another concept imported from the aviation industry to the healthcare arena is the idea that if patient safety incidents that do occur are identified and examined, then valuable lessons can be learned that may help reduce the risk of similar incidents happening again.[3,51] The intention of such *reporting and learning* systems is neatly described in Donaldson's "orange wire" analogy.[52] Here, the example was used that if a particular airplane were found to have a fault caused by a particular wire, then all planes of this type could be prevented from flying until the wire in question was replaced. The idea that this could be replicated in healthcare such that no incident became recurrent is highly attractive.

The potential benefits of a mechanism that could identify and prevent safety incidents from becoming recurrent led to the setting up of many systems for reporting of safety incidents around the world. One of the most notable is the National Reporting and Learning System in the British National Health Service (NHS), launched in 2004.[53] Over time this system has collected millions of reports of safety incidents and issued many reports, advisory notices, and alerts.[54] Unfortunately there is little sign that these have had any impact on patient safety, with reports of very similar incidents being received repeatedly.[55] The reasons for this lack of impact are multiple but include the volume of reports exceeding the resources available for investigation and analysis, the complex nature of the incidents and the number of factors that influence each one, and an absence in healthcare of the whole-system cultural change that went along with reporting and learning in the aviation arena.[56] Most safety incidents in healthcare are not amenable to a simple technical solution such as changing a wire. Rather, they require complex system-level interventions to reduce their likelihood of recurrence that are difficult to generalize from individual reports.

Despite these limitations, reporting and learning systems do play an important part in efforts to improve patient safety. Their availability to staff raises awareness of patient safety as an issue, and levels of reporting have been found to correlate with a positive safety culture within an organization.[57]

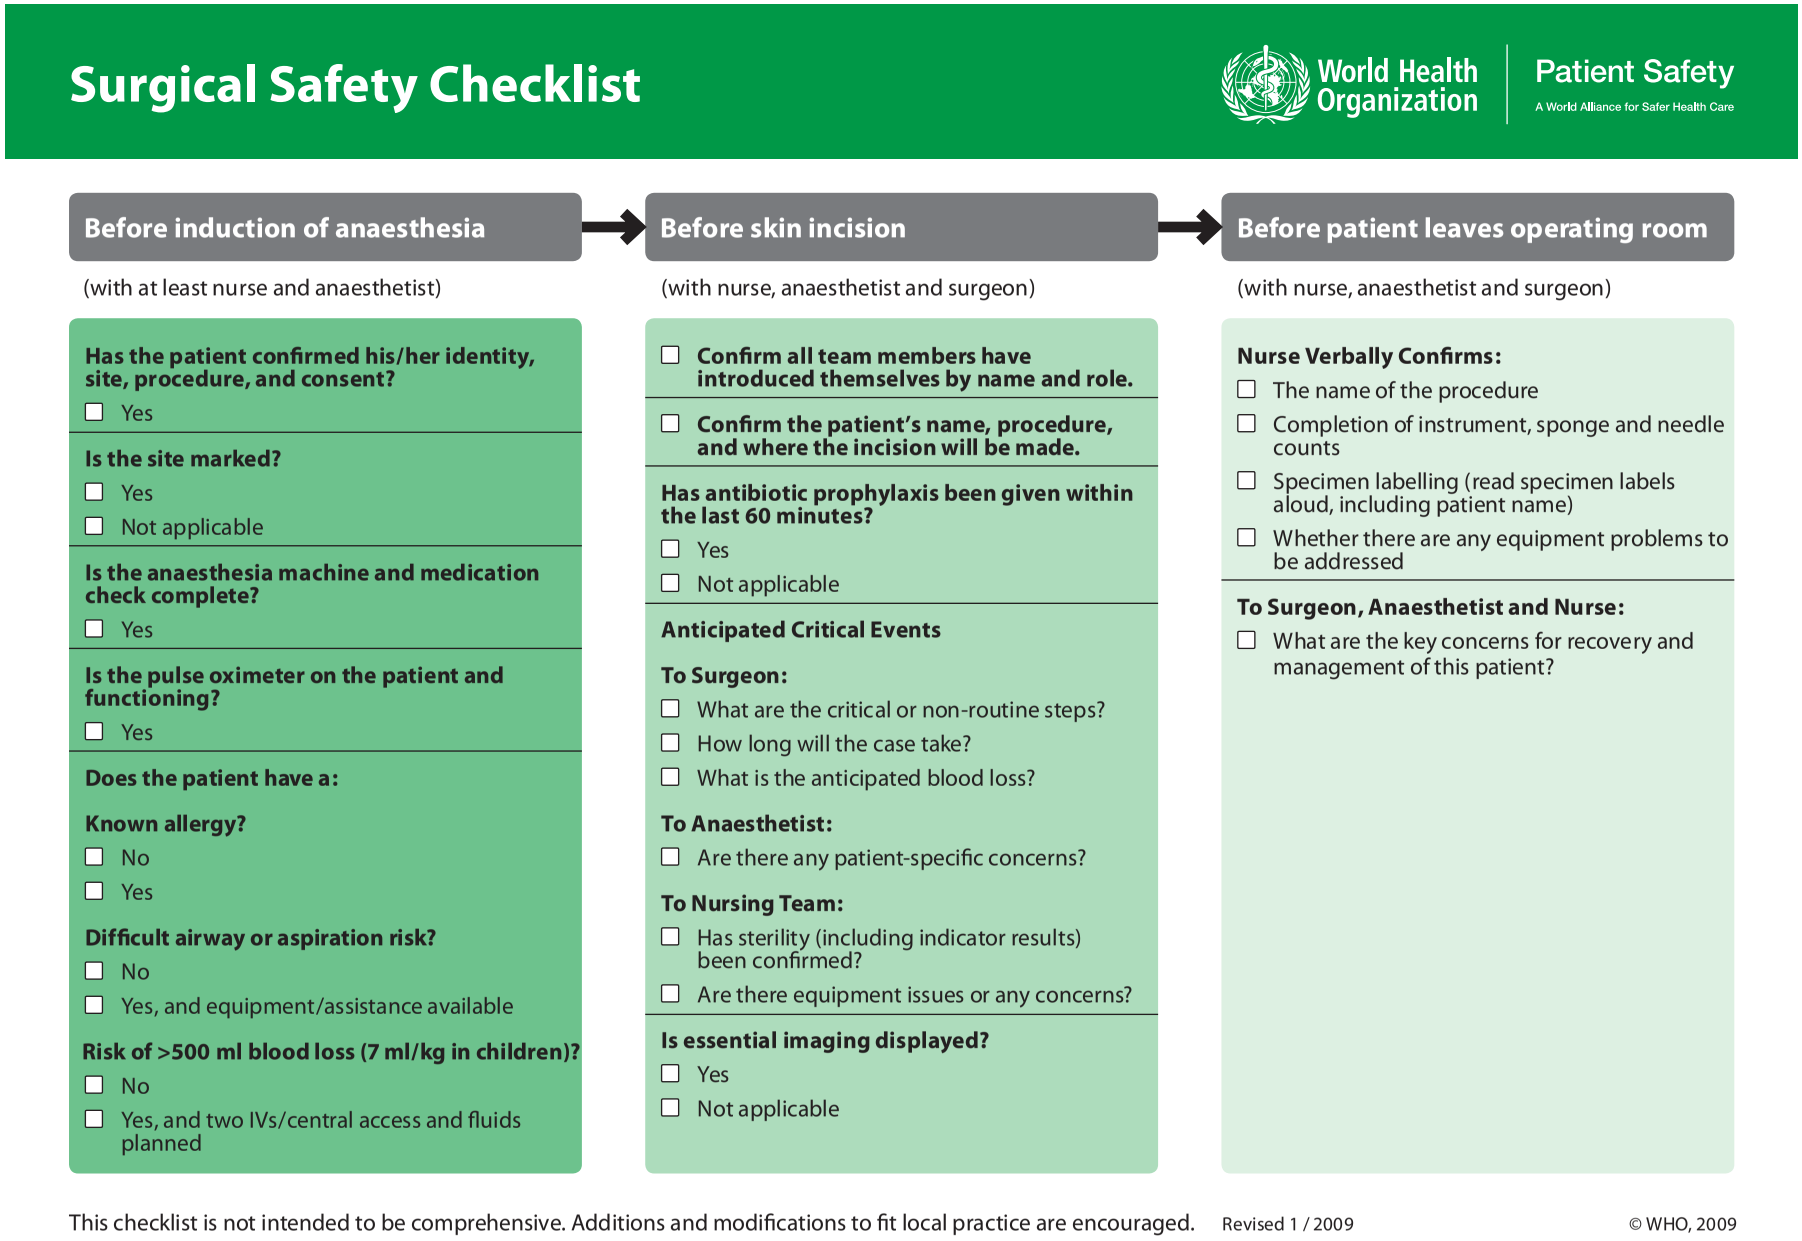

Figure 24.2 The WHO safe surgery checklist. (Reprinted with permission from World Health Organization Patient Safety, *WHO Guidelines for Safe Surgery 2009: Safe Surgery Saves Lives*, Geneva: WHO Press, 2009, 98, available at http://apps.who.int/iris/bitstream/10665/44185/1/9789241598552_eng.pdf, accessed 8th March 2016.)

Improvements in the way in which reports are collected, investigated, and acted upon may lead to reporting and learning becoming a powerful tool in improving safety in healthcare.[56]

Nontechnical skills

Traditional surgical training has focused on the technical aspects of surgical practice. Surgical trainees are required to demonstrate that they have had exposure to sufficient numbers of cases relevant to their practice, especially important in a discipline such as newborn surgery that deals largely with a collection of rare conditions. They are expected to demonstrate their competency in specific procedural skills such as tissue dissection and bowel anastomosis. The mandatory examinations that they undertake test their knowledge of pathology, anatomy, and physiology and the application of this knowledge to clinical scenarios.

While all these are undeniably vital attributes for successful surgical practice, there is a growing recognition that safe surgical practice also requires the surgeon to have crucial cognitive and interpersonal skills.[58] These are known as *nontechnical* skills and can be grouped into four categories: situational awareness, decision making, communication and teamwork, and leadership.[59,60]

SITUATIONAL AWARENESS

Situational awareness relates to an individual's ability to gather and understand the information that is available to him or her and to use this awareness to predict a future state. In surgical practice, there are a huge number of sources of information, starting with clinical history taking and examination and progressing through investigation to a diagnosis and potentially surgical intervention. Intraoperatively, there are still many items of information being relayed to the surgeon that require processing. These include operative findings such as the condition of the intestine or the degree of blood loss and information from the anesthetic team on the patient's cardiorespiratory status. It is a vital skill for a surgeon to be able to remain focused on the task in hand while receiving and processing new information that may require a change to the initial plan.

DECISION MAKING

Good situational awareness allows, in turn, for sound decision making. Decision making requires the surgeon to use his or her situational awareness to consider the options available, select the most appropriate one, and then implement the chosen plan. Decision making in surgery is necessarily an ongoing process as new and changing information is made available. A combination of situational awareness and decision-making skills allows a surgeon to implement the correct management as a case develops. For example, when operating on a neonate, a choice may need to be made between attempting an intestinal anastomosis and forming a stoma, or between attempting primary closure of a gastroschisis and fashioning a silo. A safe surgeon will have the situational awareness skills to consider the operative findings, the current condition of the patient, and his or her own abilities in order to deploy his or her decision-making skills and take the correct path.

COMMUNICATION AND TEAMWORK

At all stages in the care of a newborn surgical patient, a key nontechnical skill is excellent communication. The surgeon must communicate with many different parties including the following; the patient's family, medical colleagues also caring for the patient, anesthetic colleagues, theatre staff, and surgical colleagues. Breakdown in communication is a common factor in many safety incidents, particularly those occurring intra-operatively,[61,62] and good communication is a skill that can be learned. There are several communication models that can be deployed to improve information exchange and ensure a shared understanding within the team.[63,64] Also vital to effective communication is ensuring that all team members can speak up when they have concerns.[65] This requires the surgeon to flatten traditional hierarchies and make himself or herself available to receive critical information, regardless of the source. The requirement of the WHO safe surgery checklist for all team members to introduce themselves by name and role is a simple way to promote open communication within the operating theatre.

LEADERSHIP

The final category of nontechnical skill, leadership, overarches situational awareness, decision making, and communication. An effective surgeon is, by necessity, the leader of a team caring for a patient, retaining the moral responsibility for the overall care of the patient. This calls for skill in setting and maintaining standards, supporting others in meeting these standards, and coping in an exemplary way as an individual, even under pressure.

SUMMARY AND CONCLUSIONS

Unfortunately, despite the vast amount of work done in the field of patient safety and our greater understanding of the nature of safety incidents, it is difficult to demonstrate a reduction in safety-related harm across healthcare provision as a whole.[66] There are just a few interventions that have robust evidence for improving safety in surgical practice.[67] These include the use of checklists and care pathways, as already described, particularly where this is linked to team training processes. Reporting surgical outcome data to a central audit is also associated with a reduction in adverse events, as is subspecializing within a surgical discipline, which is associated with fewer technical complications.

Every surgeon practicing newborn surgery has the responsibility to protect the safety of his or her patients. In order to do so, he or she should do the following:

- Ensure that surgery only takes place in an environment with the infrastructure required for this highly specialized work, including essential equipment, personnel, and other support services
- Engage proactively with measures to improve patient safety, including reporting and learning systems and safety checklists
- Take part in centralized data collection processes
- Undertake training in nontechnical skills that will complement their technical abilities
- Encourage and maintain open communication throughout the teams they work in
- Be honest and open about their own abilities and only practice within their limitations

Minimally invasive neonatal surgery

RICHARD KEIJZER, OLIVER J. MUENSTERER, AND KEITH E. GEORGESON

INTRODUCTION

Gynecologists published the first reports on minimally invasive surgery in adults around 50 years ago. By then, it was mainly used for diagnostic procedures, because of the limitations in visualization and instrumentation. The introduction of chip cameras in the late 1980s enabled the surgeon and assistant to watch a screen and perform surgery at the same time, instead of holding a telescope and looking through a lens close to the patient. The development of better endosurgical instruments enabled surgeons to perform a variety of laparoscopic procedures including appendectomies, cholecystectomies, fundoplications, and more advanced operations. However, due to the lack of instruments, endoscopes, and trocars of appropriate size, the acceptance of minimally invasive surgery in the pediatric population in general, let alone in neonates, took longer than in adults. Recently, the development of smaller, shorter, and more durable instruments along with improved optical equipment has allowed pediatric surgeons to perform more complex endosurgical procedures in young children and newborns.[1]

This chapter reviews the current practice of minimally invasive neonatal surgery and reflects on potential future developments in this field.

THORACOSCOPY

The first experience with thoracoscopic procedures in children was published 30 years ago.[2] Biopsies of pulmonary lesions, both primary and metastatic in origin, are the most frequently performed thoracoscopic surgical procedure in children (reviewed in Karpelowsky[3]). With the advancement of experience and again, better equipment, more sophisticated procedures such as pulmonary resections and the repair of esophageal atresia (EA) with or without tracheoesophageal fistula (TEF) have been embraced by the pediatric surgical community. Compared to open thoracotomy, the potential advantages of a thoracoscopic approach are the muscle-sparing nature of the procedure, decreased the risk of nerve injury, and less secondary scoliosis in the long-term.[3]

Physiology and anesthetic considerations

The introduction of automatic carbon dioxide (CO_2) insufflation in the early 1960s created the necessary working domain to facilitate endoscopic surgical procedures. In most thoracoscopic cases, gentle insufflation of CO_2 to a maximum pressure of 4–5 mm Hg using a low flow of 1 L/min compresses the lung enough to allow access to most structures in the chest. Single-lung ventilation, which is more easily established and used in adult thoracoscopy, is rarely necessary in young children and neonates. In neonates, methods for single-lung ventilation are very limited. In those cases where single-lung ventilation is desired, a small Fogarty catheter has been placed into the ipsilateral main stem bronchus and gently inflated, blocking gas exchange to that lung.[4] Excellent communication between the surgeon and anesthesiologist is mandatory, as the establishment of an artificial capnothorax may change physiologic parameters. If anticipated, a higher end-tidal CO_2 can be overcome by increasing the ventilatory rate, and decreased venous return can be counteracted by appropriate volume replacement.[5] Although described in adults, the development of CO_2 embolism is exceedingly rare in the pediatric population.

Diagnostic thoracoscopy and biopsy or resection of pulmonary lesions

Improvement in the resolution of diagnostic imaging techniques, such as computerized tomography (CT) scanning and magnetic resonance imaging (MRI), along with the capability to produce multiplanar reconstructions in any three-dimensional plane, has made thoracoscopy almost obsolete for the mere assessment of intrathoracic anatomy. However, the good visualization and excellent access to

nearly all intrathoracic lesions have resulted in the replacement of most open lung biopsies by the thoracoscopic technique. In fact, thoracoscopic lung biopsy and the resection of pulmonary lesions are the most commonly performed thoracoscopic operations in neonates. In many cases, small pulmonary lesions are readily identified and isolated from the rest of the lung using a Roeder loop (Endoloop, Ethicon San Angelo, Texas, USA). After placing the suture tightly around the base of the lesion, the tissue is excised sharply peripheral to the loop and retrieved through one of the trocar sites. In larger children, a stapler can be used to transect the lung central to the lesion. Larger pulmonary lesions, such as congenital cystadenomatoid malformations and congenital lobar emphysema, should be resected by respecting the lobar or segmental anatomy. Most of the time, this entails identifying the proprietary vessels and bronchus to the affected part of the lung, and using a vessel-sealing device such as the endoscopic Ligasure (Covidien, Dublin, Ireland) or Enseal (Ethicon, Cincinnati, Ohio, USA) to divide the vessels.[6] The bronchus can be stapled, sutured, or clipped. We prefer to leave a chest tube in place through one of the trocar sites for 24 hours after the procedure, but this is dependent on the surgeon's preference.

Mediastinum

The thoracoscopic approach to mediastinal masses such as esophageal duplication cysts, bronchogenic cysts, and extralobar sequestrations is very useful for several reasons. Visualization of adjacent anatomical structures is usually excellent due to the magnification of the video image (Figure 25.1). Furthermore, the anatomy of the mediastinum is usually well defined, and some lesions tend to be well vascularized.

During esophageal duplication cyst resection, opening of the esophagus is common, since the cyst and the esophagus often share a common wall. Therefore, the esophageal defect should be closed or reinforced using interrupted absorbable sutures. A dilator or endoscope can be placed inside the esophagus to decrease the risk of esophageal injury.

Closure of patent ductus arteriosus and aortopexy

The first reports on the thoracoscopic closure of patent ductus arteriosus (PDA) originate from the early 1990s.[7] Improvements in technique and instruments have made it possible to safely perform closure of a PDA thoracoscopically in neonates with a birth weight as low as 1500 grams. However, potential complications with the thoracoscopic approach and the safety and excellent outcome of open PDA ligation have prevented both the thoracoscopic and interventional approaches from being universally accepted.

Tracheomalacia, an intrinsic weakness of the tracheal wall causing the airways to collapse during expiration, is usually a benign, self-limiting condition that improves as the infant matures. In some cases, especially when associated with other intrathoracic lesions such as EA, the gas exchange is compromised, and the tracheomalacia should be treated with an aortopexy. It is important to rule out a vascular cause for the patient's stridor (such as a vascular ring or sling) by esophagram or angiography. Once all other causes are excluded, a thoracoscopic aortopexy can be performed using a triangular position of the camera and instruments in the anterior midline and anterior axillary line; the surgeon generally uses three interrupted sutures to pexy the aorta to the sternum.[8]

Esophageal atresia

Thoracoscopic repair of TEF and EA is considered one of the most technically challenging minimally invasive procedures in pediatric surgery due to the limited domain inside the neonatal thorax and the technical difficulty of making a good and trustworthy anastomosis between the proximal pouch and the distal fistula. Consequently, complications observed following thoracoscopic repair are often related to the anastomosis, such as anastomotic leakage and stricture.[9] Advocates of the thoracoscopic approach acclaim the excellent visualization of the anatomy and warn against the long-term disadvantages of repair using a thoracotomy, such as asymmetry of the chest wall, scoliosis, or a winged scapula as the consequence of nerve injury.[10] A recent randomized controlled clinical study comparing open versus thoracoscopic repair of TEF/EA expressed concerns about the effects of thoracoscopy on blood gases during the repair and recommended further evaluation.[11]

For EA and fistula repair, echocardiography is used to determine whether there is a right- or left-sided aorta. The esophagus is approached from the contralateral side. The patient is positioned in a lateral decubitus position, slightly prone, to allow gravitational retraction of the lungs away from the posterior mediastinum. Three triangulated trocars are used, with an additional access site if needed for retraction. In most cases, the azygos vein is divided, and the pleura is opened over the fistula. The fistula is suture-ligated or clipped, both ends of the esophagus are mobilized just enough to facilitate the anastomosis, and the anastomosis is performed (Figure 25.1a–d).

Congenital diaphragmatic hernia

In contrast to TEF repair, minimally invasive repair of congenital diaphragmatic hernia (most frequently Bochdalek hernias) has gained more popularity among pediatric surgeons during the past few years. Whereas the first reports of both laparoscopic and thoracoscopic repairs were mainly anecdotal and described the procedure in older infants and children, the indication for thoracoscopic repair has shifted to symptomatic congenital diaphragmatic hernias in newborns.[12] Even repair of the diaphragmatic defect using a patch has been well described with good results.[13] Most

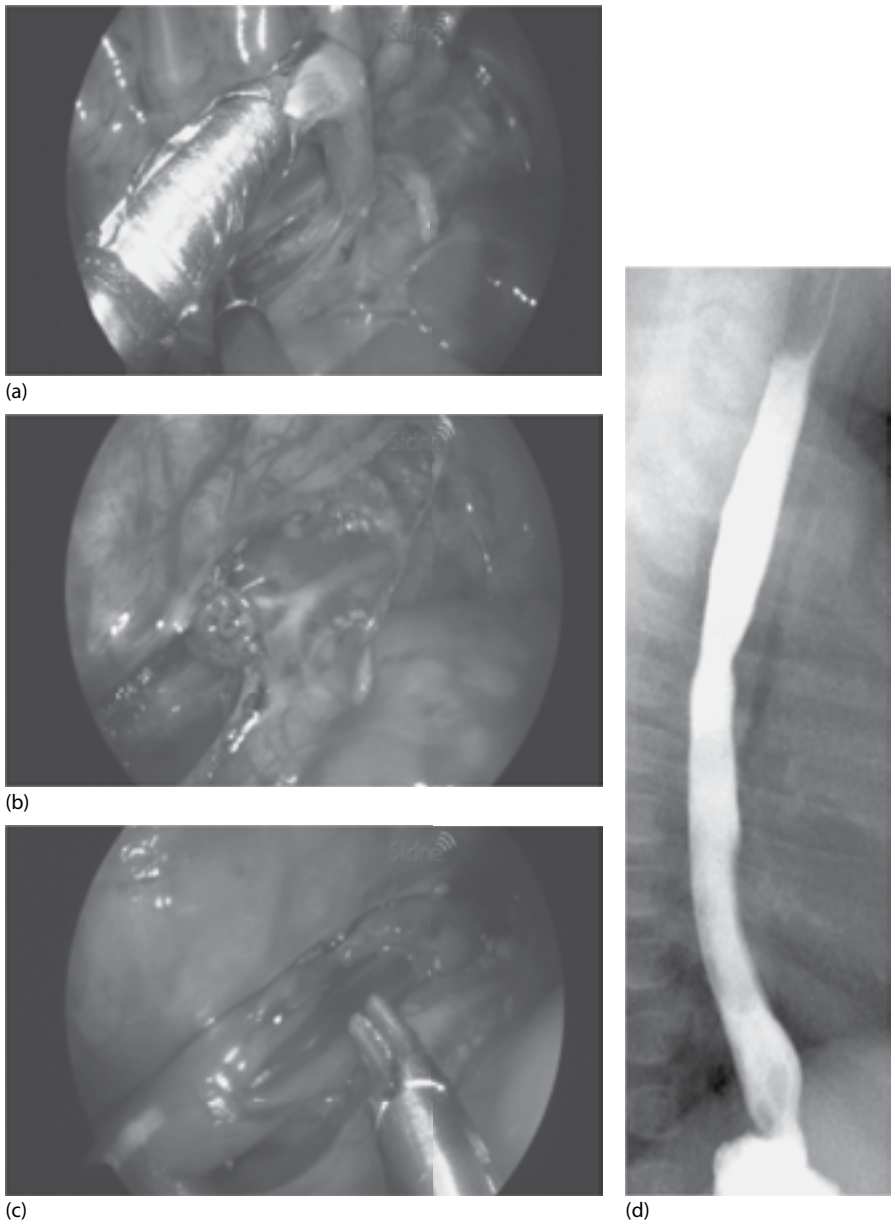

Figure 25.1 Repair of esophageal atresia with distal tracheoesophageal fistula. The fistula is identified, **(a)** dissected, ligated, **(b)** and divided. **(c)** Subsequently, the anastomosis is performed over an orogastric tube. **(d)** Postoperative results are generally excellent and comparable to those of the open technique.

likely, the positive outcomes in the latest studies reflect the completion of learning curves by those pediatric surgeons who perform the procedure frequently. The same randomized controlled trial expressing concerns about the thoracoscopic repair of TEF/EA recommended against the use of thoracoscopy with CO_2 insufflation for the repair of CDH as a result of the associated prolonged and severe hypercapnia and acidosis.[11] Due to the associated persistent pulmonary hypertension and pulmonary hypoplasia, many logical outcome measures to test the superiority of the open versus minimally invasive technique, such as ventilation days or length of stay, will be mainly influenced by the degree of any associated conditions.

The thoracoscopic approach is generally preferred over a purely laparoscopic repair of a congenital diaphragmatic hernia. In some cases, we have used simultaneous thoracoscopic and laparoscopic cameras to aid with the anatomic reduction of the viscera, and to rule out injury to the intra-abdominal organs during suturing. The patient is positioned in a contralateral decubitus position, and an axillary triangulated trocar configuration is used. The most lateral suture often has the most tension, and a transcostal suture placed through a small stab incision through the lower chest is helpful in facilitating a complete and secure closure of the diaphragmatic defect. Figure 25.2 illustrates a standard diaphragmatic hernia repair.

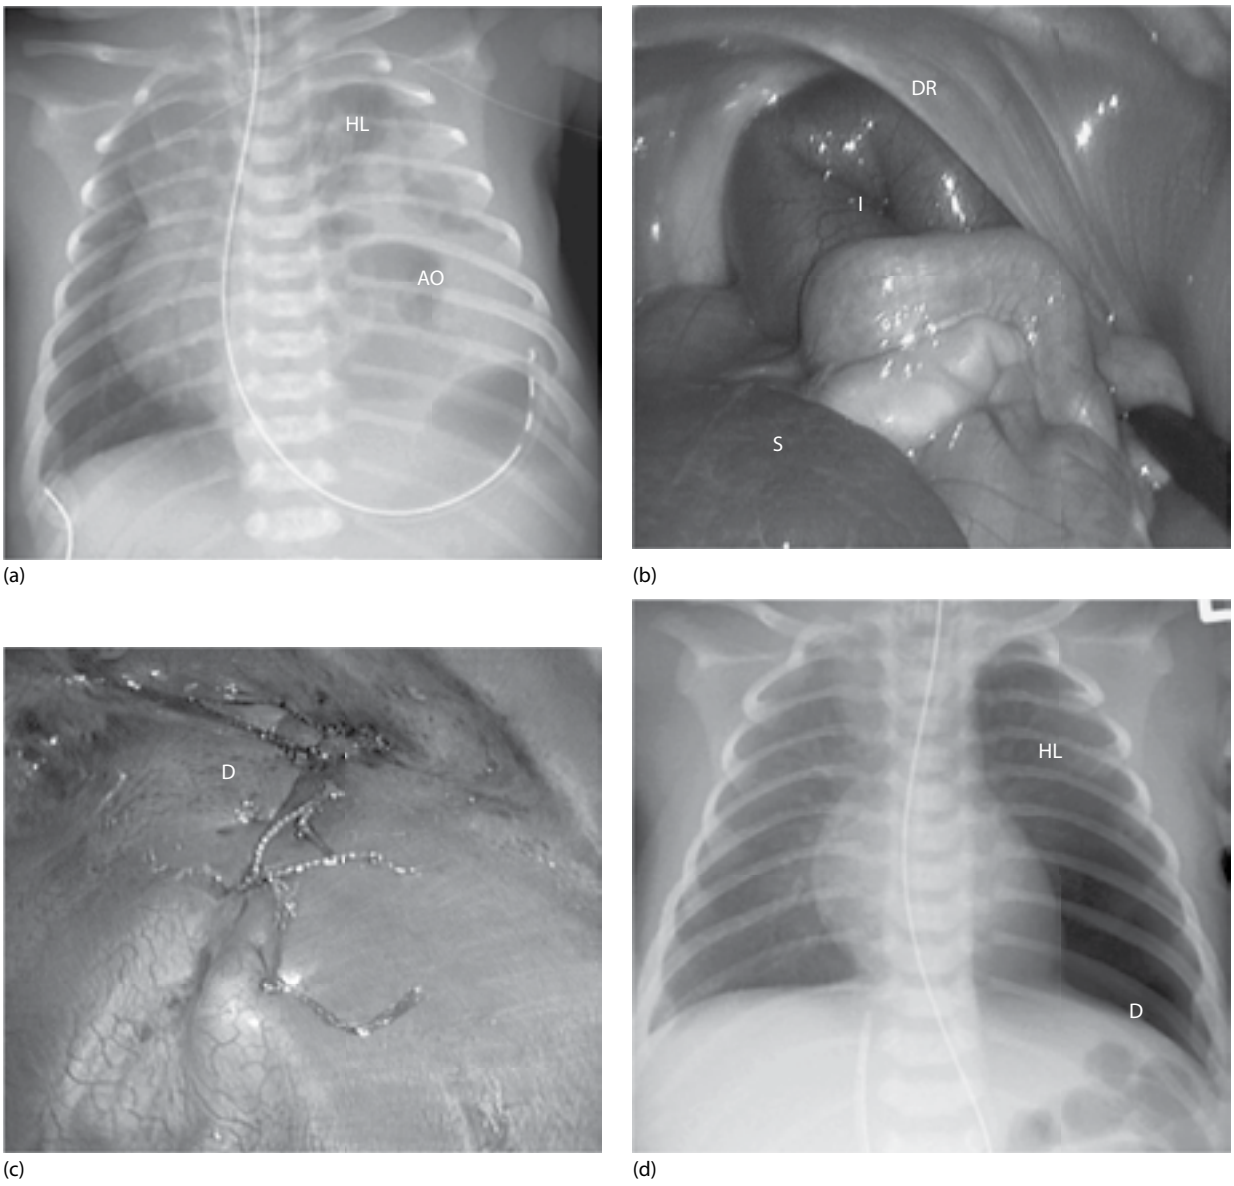

Figure 25.2 Closure of congenital diaphragmatic hernia: **(a)** Preoperative chest x-ray of an infant with left-sided congenital diaphragmatic hernia. **(b)** Thoracoscopic intraoperative view looking down on the abdominal organs (intestines and spleen) that herniated through the diaphragmatic defect into the thorax. **(c)** Diaphragmatic defect has been closed using interrupted sutures. **(d)** Postoperative chest x-ray. Note the hypoplastic lung in the top of the thorax and the reconstructed dome of the diaphragm. Abbreviations: AO, abdominal organs; D, diaphragm; DR, diaphragmatic rim; HL, hypoplastic lung; I, intestines; S, spleen.

LAPAROSCOPY

Physiology of pneumoperitoneum

While CO_2 insufflation into the thorax may be associated with considerable changes in the physiology, CO_2 insufflation to establish a capnoperitoneum is often very well tolerated by most neonatal patients. Still, the pressures and flows should be kept at the minimum necessary to guarantee adequate working space and visualization. In neonates, we use pressures of 6–8 mm Hg and flows between 1 and 2 L/min. Insufflated CO_2 is absorbed more readily into the bloodstream of infants, mainly due to smaller diffusion barriers and an increased peritoneal absorptive surface area in comparison to body weight. Hypercapnia and respiratory acidosis may result but can usually be overcome by increasing minute ventilation during the laparoscopic procedure.[5]

Potential adverse effects of increased intra-abdominal pressure include compression of the inferior caval vein resulting in a decrease in the venous return, as well as the upward displacement of the paralyzed diaphragm. This can result in pulmonary atelectasis that may only become clinically relevant after the resumption of spontaneous breathing. Some of these patients may require prolonged positive-pressure ventilation to recruit the collapsed pulmonary alveoli.

Abdominal access

There is no evidence that either the Veress needle technique or the Hasson techniques are safest for initial access to the abdomen in children. As long as one adheres to the fundamental principles of safe insertion, damage to intra-abdominal contents, including the large vessels, is rare. As in adults, abdominal access for laparoscopic procedures in newborns is usually obtained through the umbilicus. The umbilicus might be a potential source of infection after the umbilical cord has recently separated. Therefore, some surgeons prefer an incision above or below the umbilicus instead. Following the installation of local anesthetic, and after vertically incising the skin in the umbilical scar, we prefer to enter the abdomen using the naturally occurring small umbilical hernia defect to place a 5 mm radially expanding trocar. Reusable trocars can subsequently be inserted safely under direct vision where required. When placing the trocars, the surgeon should keep the triangulation principle in mind: left-hand instrument, camera, and right-hand instrument should form a triangle with the target organ in one axis with the surgeon and the camera.

Dislodgement of the trocars can be a major problem and nuisance during laparoscopic surgery in neonates and small children.[14] To prevent this, we place radially expanding 5 mm trocars through small incisions that hold them in place. Nonexpanding trocars are secured to the skin with a silk stitch in place using a red rubber cuff around the shaft of the trocar. The trocar can be moved in and out relative to the cuff using a mosquito clamp when required during the operation.

Pyloromyotomy

Laparoscopic pyloromyotomy is one of the few laparoscopic procedures that have recently been demonstrated in a large multicenter randomized clinical trial to be superior to the open classical approach. The conclusion of this hallmark study by Hall et al. was that both open and laparoscopic pyloromyotomy are safe, but that time to achieve full enteral feeding was better in the laparoscopic group. Therefore, the authors recommend laparoscopic pyloromyotomy in centers with sufficient laparoscopic experience. Interestingly, this trial was stopped by the data monitoring and ethics committee because of significant treatment benefit in the laparoscopy group at the interim analysis. Another prospective randomized trial concluded that the laparoscopic approach does not affect the length of recovery or complication rate.[15] However, the laparoscopic operation was associated with less pain and fewer episodes of emesis. Also, the authors mentioned the cosmetic benefit of the laparoscopic approach, when compared with a right upper quadrant incision.

Although the laparoscopic approach is associated with a considerable learning curve[16] that may have resulted in more incomplete pyloromyotomies in the first published patient series, recent randomized controlled clinical trials have failed to show a difference in this regard. In summary, the advantages of laparoscopic versus open pyloromyotomy appear to be less postoperative discomfort, a faster recovery, shorter length of stay, and better cosmesis.[17] Recently, a single-incision laparoscopic approach has been described.[18]

Gastrostomy

Gastrostomy placement to provide total or supplemental nutrition is a common procedure in infants and children. In many centers, gastroenterologists (sometimes in close collaboration with the pediatric surgeons) perform most of these feeding tube placements using the percutaneous endoscopic gastrostomy tube. The procedure combines flexible esophageal gastroduodenoscopy with percutaneous puncture of the stomach to place a gastrostomy tube that can later be replaced by a gastrostomy button device. However, the percutaneous endoscopic technique has significant drawbacks and a relatively high complication rate, including bowel perforation.[19] Therefore, we prefer the laparoscopic, single-incision technique for gastrostomy tube placement that has been developed in our center.[20] This procedure allows visualization of the stomach and abdominal wall during the entire process, avoiding injury of adjacent viscera. It also permits primary placement of a gastrostomy button device, which is preferred by the caregivers.

Fundoplication

The laparoscopic Nissen fundoplication quickly gained popularity for treatment of symptomatic gastroesophageal reflux disease (GERD). Good intraoperative visibility of the hiatus, excellent postoperative cosmesis, less pain, and reduced length of stay, as well as good efficacy combined with a low morbidity and mortality, have made this operation the standard of care. A recent randomized controlled trial demonstrated that laparoscopic fundoplication was associated with a higher recurrence rate of GERD.[21] In our practice, indications for a laparoscopic Nissen fundoplication are a failure of medical therapy for GERD and inability to tolerate gastric bolus feeds, either via the orogastric route or through an existing gastrostomy. The laparoscopic technique for gastrostomy placement described previously assures that it is in a good location on the anterior aspect of the stomach, close to the greater curvature, and about two-thirds down from the fundus to the antrum. In such cases, a later laparoscopic fundoplication is easily achieved if necessary. We perform a 360-degree wrap around the lower esophagus and the gastroesophageal junction with minimal dissection of the hiatus, as this has been shown to decrease failure rate.

Inguinal hernia

Inguinal hernia repair is one of the most common operations performed in newborns. The laparoscopic repair of an inguinal hernia involves the percutaneous or

transabdominal suturing of the peritoneum of the internal inguinal ring. Randomized controlled trials have demonstrated that laparoscopic bilateral hernia repair is faster than open, whereas unilateral repair showed no difference.[22] Recurrence rates between open and laparoscopic repair do not differ. At this point, no strong recommendation based on the available literature can be made, and the results of prospective comparative studies are awaited.

Endorectal pull-through

Following a biopsy-proven diagnosis of Hirschsprung disease, a primary one-stage laparoscopic endorectal pull-through in the neonatal period is currently considered the standard of care by most pediatric surgeons.[23] A systematic review and meta-analysis did not show a difference between a laparoscopic and transanal endorectal pull-through for rates of enterocolitis, incontinence, or constipation.[24] Naturally, significant comorbidities or severe enterocolitis should be absent in this circumstance. The procedure is performed using three to four small abdominal ports, either in a triangular configuration or through the same skin incision in the umbilicus for a single-incision approach.[25] The transition zone is estimated by its morphology, and laparoscopic seromuscular biopsies are obtained. In patients with a rectosigmoid colon transition zone, the intra-abdominal portion of the aganglionic bowel is devascularized using hook electrocautery. In patients with longer segments of an aganglionic colon, a pedicle preserving the marginal artery is fashioned as far proximal as necessary to bring the colon pedicle down without tension to form the neorectum. The rectal mobilization is performed transanally using an endorectal sleeve technique. The anastomosis is performed transanally 0.5 cm above the dentate line. Successful methods for performing laparoscopy-assisted Duhamel and Swenson pull-through procedures have also been reported in neonates. The laparoscopic-assisted endorectal pull-through has several advantages over a purely perineal approach. For one, the transition zone is histologically proven before the diseased bowel is resected. Furthermore, mobilization of the colon helps preserve a normal anorectal angle, which is essential for later continence.

Using similar principles, a minimally invasive technique for the correction of intermediate and high anorectal malformations (ARMs) has been developed in our institution: the laparoscopically assisted anorectoplasty (LAARP). Taking maximal advantage of the excellent visualization of the pelvic musculature from the inside using the laparoscope, the distal colon and fistula are dissected and divided. An expanding trocar is then placed through the muscle complex after identification using the electric nerve stimulator. Placement of the trocar is further aided by transillumination of the endoscope's light.[26] In comparative studies, functionality and continence for both the perineal and laparoscopic operation are comparable.[27]

Malrotation

Incomplete rotation or malrotation of the intestines results in a malposition and nonfixation of the duodenum and terminal ileum, and this situation predisposes the patient to midgut volvulus. Principles of the laparoscopic approach are similar to the open approach and include counterclockwise derotation of the intestines in case of a volvulus and release of the Ladd bands starting distal to the pylorus and continuing distally until the mesenteric stalk is widened; and the whole duodenum, as well as the jejunum, is located on the right side, and the cecum is allowed to fall over to the left side of the abdomen. This operation is usually performed with an incidental appendectomy as described by Ladd. One of the larger series comparing outcomes between treatment with laparotomy versus laparoscopy concluded that laparotomy was associated with a high rate of small bowel obstruction, more complications, and longer length of hospital stay, without an increased risk of recurrent volvulus.[28]

Duodenal atresia

Smaller laparoscopic surgical instruments have enabled pediatric surgeons to perform more sophisticated laparoscopic procedures such as duodenal atresia repair. The first reports of successful laparoscopic duodenal atresia repair were published at the beginning of this century. Using intracorporeal suturing, a diamond-shaped anastomosis is performed similarly to the open approach to open duodenal atresia repair. We prefer to use a running suture for the back wall and interrupted sutures in the front. Only a few small case series have been published so far, and a number of complications have been described. Therefore, this procedure should be reserved for very experienced pediatric endosurgeons, and a low threshold for conversion, in our view, is warranted.

Biliary pathology

Large series of laparoscopic choledochal cyst excision have been published in the literature with excellent results comparable to the open approach. The surgical principles are equivalent to those of the open procedure. Retraction of the gallbladder using a transabdominal suture in the upper right quadrant aids with the dissection. After resection of the cyst, a Roux-en-Y loop of bowel is created either intracorporeally or by exteriorizing the proximal small intestine through the umbilical incision. The anastomosis between the Roux loop and the proximal common bile duct is performed using an intracorporeal suturing technique (Figure 25.3a–d).

Although laparoscopic and robot-assisted Kasai procedures have been performed and reported, a higher failure rate has been reported compared to the open operation.[25] The reason for these findings is still unclear. In a sentinel vote at the 2007 IPEG (International Pediatric Endosurgery Group) meeting in Buenos Aires, the attending endoscopic

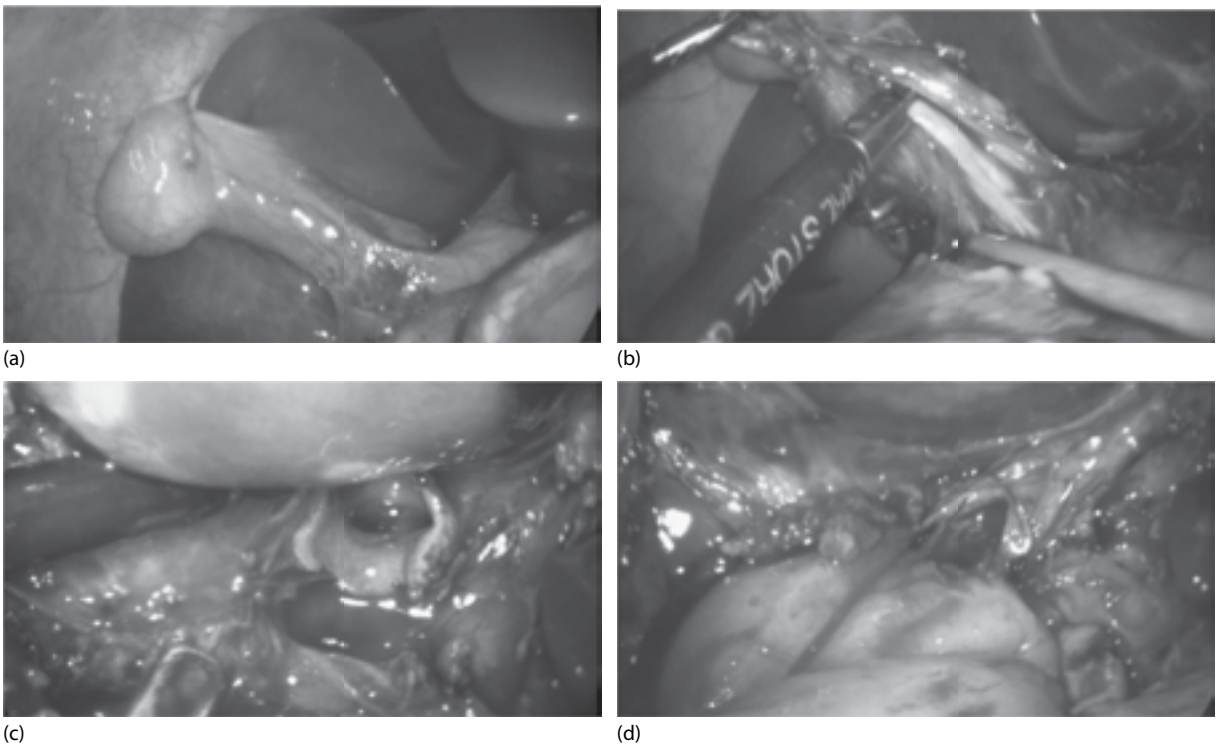

Figure 25.3 Resection of Type 1 choledochal cyst: **(a)** The gallbladder is restricted by a transabdominal suture, exposing the common bile duct below. **(b)** The common bile duct is transected proximally, and then **(c)** the cyst itself is resected. **(d)** After creation of a Roux-en-Y limb, an enterobiliary anastomosis is performed.

pediatric surgeons agreed to perform minimally invasive Kasai operations only in well-controlled study protocols until more information is available. A recent meta-analysis confirmed this recommendation.[29]

Pelvic pathology

With the improvement of prenatal ultrasound screening, pediatric surgeons see more neonates with enlarged ovarian cysts these days. Cysts with a complicated or complex ultrasound pattern and those over 4 cm in diameter that do not resolve spontaneously after several weeks of life warrant surgical exploration.[30] This is preferably done using laparoscopy. Serum alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (beta-HCG) levels should be checked preoperatively, and sound oncologic principles should be applied during surgery. Benign simple cysts may be drained by needle aspiration to facilitate removal through a trocar site. All other lesions can be removed using an endoscopic retrieval bag through the umbilicus or a separate, Pfannenstiel-type suprapubic incision.

Another pelvic pathology that can benefit from a laparoscopically assisted intrapelvic or intra-abdominal dissection is the resection of a sacrococcygeal teratoma.[31,32] More than 50% of the tumors have such an intracorporeal portion of the tumor, and dissection can be facilitated by the magnified view of the laparoscope. Control of the presacral veins can be achieved by laparoscopy, and the intra-abdominal portion of the tumor can be mobilized off surrounding structures.[33] Again, strict observance of oncologic principles is mandatory.

Future directions

In a period of only less than 25 years, minimally invasive surgery has become a major part of the practice of many pediatric surgeons. Many open procedures have been replaced or supplemented by comparable or even better minimally invasive procedures. It is hard to imagine that new developments in the field with even more minimally invasive procedures such as natural orifice transluminal endoscopic surgery (NOTES) or single-incision pediatric endosurgery (SIPES) are going to bring the same revolutionary advancement to general pediatric surgery that laparoscopic and thoracoscopic surgery have. Although the first large series of NOTES procedures (cholecystectomies through the vagina) in adults have been published recently, NOTES is still suffering from the technological difficulty of the perfect closure of the access organ that is used as the natural orifice.

In contrast, SIPES is slowly gaining more popularity, and series on several operations such as appendectomies, cholecystectomies, splenectomies, and pyloromyotomies have been published (reviewed in Bax and van der Zee,[33] Kozlov et al.[34] and Zhang et al.[35]). Introducing the camera and work instruments through the umbilicus, occasionally supplemented by a 2 mm percutaneous grasper in another

location, we have been able to safely perform over 300 such procedures, including appendectomies, Nissen fundoplications, cholecystectomies, splenectomies, pyloromyotomies, and endorectal pull-throughs for Hirschsprung disease (Figure 25.4).[36] However, our experience demonstrates that the procedures are more technically demanding because of the loss of triangulation, instrument clashing, and limited visualization. Randomized clinical trials testing SIPES versus laparoscopic surgery regarding complications, postoperative recovery, length of stay, and postoperative pain should be awaited before this technically more demanding technique can be recommended universally.

CONCLUSION

Minimally invasive neonatal surgery has become an established tool in the palette of the modern pediatric surgeon. Although the number of controlled clinical trials testing

this relatively new approach is small, more and more publications are showing a benefit of the minimally invasive approach with regard to postoperative recovery, pain, and cosmesis. Whereas costs of minimally invasive surgery have always been a concern, the equipment has become cheaper over the past few years. In fact, when costs are considered on a macroeconomical scale, shorter length of stay after a minimally invasive procedure may level or offset the balance in favor of minimally invasive surgery. Eventually, it is likely that most surgical conditions in neonates will be corrected using these techniques.

Fetal surgery

HANMIN LEE AND BENJAMIN PADILLA

INTRODUCTION

Birth defects have long captivated the human imagination. As Samuel Taylor Coleridge wrote, "The history of man for the nine months preceding his birth would be far more interesting and have events of far greater moment than all three-score and ten years that follow." Over the last 40 years, fetal diagnosis through imaging and fetal sampling has improved tremendously, allowing for earlier and more accurate diagnosis of birth defects. Surgeons are increasingly called upon for management of these anomalies before birth. In this chapter, we present general principles of fetal surgery, methods of fetal access, diseases that are amenable to fetal intervention, and a brief discussion of the future of fetal surgery.

GENERAL PRINCIPLES

Fetal intervention places both the fetus and the mother at risk. The mother gains nothing in terms of health benefits and is placed at risk of potential morbidity and mortality. The mother is an innocent bystander in the calculation of risk, with the possible benefit garnered by her unborn child. Our greatest responsibility is protecting the mother. In this light, fetal surgery is only considered for life-threatening or severely debilitating anomalies where fetal surgery shows promise of improving outcomes after thorough investigation in animal models.

A multidisciplinary approach is crucial to the success of any fetal treatment program. The team consists of perinatologists, anesthesiologists, radiologists, cardiologists, neonatologists, neurologists, geneticists, and pediatric surgeons working in concert. At the University of California, San Francisco (UCSF), all fetal referrals are discussed at a weekly meeting where imaging studies are reviewed and a consensus is reached regarding further diagnostic workup and treatment. Furthermore, the social and ethical aspects of each case are carefully weighed. A special institutional fetal treatment oversight committee reviews all fetal interventions, serving as both a quality control mechanism and ethical review body.

Since the first open fetal surgery at UCSF in 1982,[1] there have been no maternal mortalities following a fetal operation at UCSF.[2] Despite many technical advances, disruption of the membranes and preterm labor continue to be the Achilles heel of fetal surgery, resulting in premature delivery between 25 and 35 weeks gestation.[3] Multiport fetoscopic surgery has not significantly mitigated the risk of preterm labor, as membrane separation at the port sites is common.[2] Pulmonary edema associated with administration of tocolytics is the most common immediate maternal complication. Bleeding originating from the fetus, placenta, uterine wall, or maternal abdominal wall that requires transfusion is a serious although infrequent problem. Other complications include chorioamnionitis, pulmonary embolism, and deep venous thrombosis.[4] Importantly, fetal surgery does not adversely affect fertility or the ability to carry future pregnancies.[5] However, delivery of pregnancies after open fetal surgery requires cesarean section due to the risk of uterine rupture during labor.

FETAL DIAGNOSIS

Fetal ultrasound is the cornerstone of prenatal diagnosis and is a fundamental component of any fetal intervention. Routine anatomic surveys are generally conducted in the middle of the second trimester between 18 and 20 weeks gestation. Real-time fetal ultrasound identifies anatomic anomalies and provides physiologic information such as fetal heart rate, placental blood flow, and presence or absence of hydrops fetalis. Magnetic resonance imaging is increasingly used when high-resolution fetal imaging of the brain, spine, and body is needed. As many syndromes are associated with congenital heart defects, fetal echocardiography is an important diagnostic modality as well. The presence of a congenital heart defect precludes most fetal interventions (Figure 26.1).

Amniocentesis is the most widely used and accepted modality for karyotyping and DNA-based diagnosis of many genetic defects and inherited diseases. Although amniocentesis is safe, it cannot be used until the second trimester. Chorionic villus sampling can be performed between 10 and 13 weeks gestation, yet has a greater risk of pregnancy loss.[6] A number of noninvasive prenatal screening tests were developed to avoid the risk of pregnancy loss. A major breakthrough in noninvasive prenatal diagnosis came when cell-free DNA could be isolated from maternal blood and analyzed using polymerase chain reaction (PCR) technology for specific chromosomal sequences.[7] This technique allows for detection of paternally inherited and de novo genetic disorders as well as trisomy 21, 18, and 13, and fetal gender. Increasingly, microarrays are being used to gain further genetic information about fetuses.

FETAL ACCESS

There are three general methods of accessing the fetus: (1) percutaneous access, (2) minimally invasive fetoscopy, and (3) open hysterotomy. All three approaches require preoperative and intraoperative ultrasonography to define the anatomy, determine the position of the fetus, delineate the location of the placenta, and monitor the fetal heart rate and umbilical artery blood flow during the operation. In percutaneous and fetoscopic operations, ultrasound is of particular importance due to the lack of direct exposure of the fetus and uterus.

Maternal positioning is usually supine, with the left side down to minimize compression of the inferior vena cava. Depending on the nature of the intervention, maternal anesthesia can be local, spinal, epidural, or general. Fetal anesthesia in the form of an intramuscular injection of an opiate and nondepolarizing muscle relaxant is given when operating directly on the fetus.[8,9]

Ultrasound-guided, percutaneous procedures are performed via small skin incision in the maternal skin. These require real-time ultrasound, as the only visualization of the fetal and maternal anatomy is via ultrasound images. Through this type of access, cystic structures, ascites, the bladder, or pleural fluid can be aspirated or drained into the amniotic space with the placement of a shunt. In addition, a radiofrequency ablation (RFA) probe can be deployed into the amniotic space for the treatment of various complications of twin gestation. The needles used to access the fetus are approximately 1.5–2 mm in diameter, resulting in minimal maternal morbidity.[10,11] Fetal cardiac valvuloplastes are also performed with ultrasound and echo guidance.[12]

Fetoscopic procedures are generally performed via a 3–4 mm port that accommodates a 3 mm fetoscope with a 1 mm working channel. Ultrasonography is essential for identifying a uterine "window" that is devoid of placenta in order to reduce the risk of maternal bleeding, placental abruption, and fetal morbidity. When using only the fetoscope, we usually make a 3 mm skin incision on the mother's abdomen to access the uterus rather than making a maternal laparotomy. Occasionally, the amniotic fluid is not clear enough to allow for a good image via a small endoscope. In these cases, the view is improved by performing amnioexchange with warmed crystalloid solution.[13]

Open fetal surgery requires general anesthesia and preoperative indomethacin and high-dose inhalational agents to maintain uterine relaxation.[8,9] The uterus is exposed through a low transverse abdominal incision. Ultrasonography is used to map out the placenta. A posteriorly positioned placenta allows for an anterior hysterotomy. An anteriorly positioned placenta requires elevation of the uterus out of the abdomen for a posterior hysterotomy. The hysterotomy should be a minimum of 5 cm from the edge of the placenta to prevent placental abruption and to facilitate closure of the hysterotomy. The hysterotomy is made with specially designed absorbable uterine staples that provide hemostasis and seal the membranes. Metallic stapling devices are not used as the metallic staples in the uterine wall act as in an intrauterine device and adversely affect future fertility after open fetal operations.[14] The fetus is monitored with continuous pulse oximetry and echocardiography. Warm saline solution is continuously infused around the fetus to prevent hypothermia and compression of the cord vessels. Fetal exposure is limited to the body part of interest. After completion of the fetal operation, the fetus is returned to the uterus, the amniotic fluid is replaced, and the hysterotomy is closed with running and interrupted absorbable suture. Postoperatively, tocolytics are administered, and the mother is monitored for contractions. The fetal heart rate is monitored, and daily echocardiogram is used to monitor for ductus arteriosus constriction and right-sided heart failure.

The ex utero intrapartum treatment (EXIT) procedure was developed as a bridge between fetal and postnatal therapy. Anesthesia is delivered to both mother and fetus, and a hemostatic hysterotomy is made. The uterus is completely relaxed to prevent placental separation, and the umbilical cord is not clamped. Fetal circulation is preserved, and the fetus is maintained on full placental support until the airway can be secured (Figure 26.2). The EXIT procedure has been used to reverse tracheal occlusion and endotracheal intubation, repair the trachea, place a tracheostomy tube, resect large cervical tumors, and place cannulas for immediate extracorporeal membrane oxygenation (ECMO).[15]

Figure 26.2 Fetal laryngoscopy after maternal hysterotomy during an EXIT procedure in a fetus with a large cervical neck mass.

ANOMALIES AMENABLE TO FETAL SURGERY

The current applications of fetal surgery are outlined in Table 26.1. Almost all fetal therapies are directed at lethal conditions, the notable exception being myelomeningocele (MMC).

Table 26.1 Fetal anomalies currently amenable to fetal intervention

Defect	Natural history	Fetal intervention
Urinary obstruction (urethral valves)	Renal failure, pulmonary hypoplasia	Percutaneous vesicoamniotic shunt
Congenital pulmonary airway malformation	Hydrops, death	Steroids, thoracoamniotic shunt, open pulmonary lobectomy
Congenital diaphragmatic hernia	Pulmonary hypoplasia, pulmonary hypertension	Temporary fetoscopic balloon tracheal occlusion
Sacrococcygeal teratoma	Hydrops, death	Open resection, vascular occlusion (RFA, alcohol)
Twin–twin transfusion syndrome[a]	Hydrops, death, neurologic damage to survivor	Fetoscopic laser ablation of placental vessels
Acardiac/anomalous twin (TRAP)	Death, neurologic damage to survivor	Cord occlusion/division, RFA
Cardiac valvular obstruction	Hypoplastic heart	Balloon valvuloplasty
Congenital high airway obstruction syndrome (CHAOS)	Hydrops, death	Fetoscopic tracheoplasty, EXIT
Cervical teratoma	Hydrops, death	Open resection, EXIT
Myelomeningocele[a]	Hydrocephalus, paralysis, neurogenic bowel/bladder	Open repair

[a] Intervention studied in large prospective randomized clinical trial.

Congenital diaphragmatic hernia

Despite advances in neonatal respiratory support, survival for children born with congenital diaphragmatic hernia (CDH) remains only 60%–70% throughout the United States. Herniation of the abdominal viscera into the chest interferes with normal lung development, resulting in pulmonary hypoplasia and pulmonary hypertension.[16,17] It was hypothesized that in utero intervention would allow for increased antenatal lung growth and improved survival postnatally.[18] In a fetal lamb model, compression of the lungs during the last trimester, either with an intrathoracic balloon or by creation of a diaphragmatic hernia, resulted in fatal pulmonary hypoplasia. In addition, removal of the compressing lesion allowed the lung to grow and develop sufficiently to permit survival at birth.[19]

It was important to identify the patients who might benefit the most from in utero CDH repair. Fetal ultrasound was used to stratify the severity of CDH. Liver herniation into the chest is the most important prognostic factor for CDH. In our experience, survival was 100% in fetuses with CDH without liver herniation and 56% in fetuses with CDH with liver herniation into the chest.[20,21] To further stratify risk in fetuses with liver herniation into the chest, the *lung-to-head ratio* (LHR) was developed. The LHR is calculated as the area of the contralateral lung at the level of the cardiac atria divided by the head circumference. This LHR value statistically correlated with survival in fetuses with liver herniation: 100% survival with an LHR greater than 1.35, 61% survival with an LHR between 0.6 and 1.35, and 0% survival with an LHR less than 0.6.[21]

Initial attempts at fetal surgery to treat CDH involved in utero diaphragmatic hernia repair. Although CDH repair via open hysterotomy proved feasible, there was no survival benefit. The benefit of in utero CDH repair was likely offset by the deleterious effect of premature delivery.[22] Efforts were redirected at finding a strategy for promoting in utero lung growth. The observation that fetuses affected by congenital high airway obstruction develop hyperplastic lungs[23] led to a series of animal studies that proved that tracheal occlusion leading to the accumulation of pressurized fluid in the airway results in lung growth.[24] The preliminary studies examined the effect of extrinsic tracheal occlusion by the in utero placement of an obstructing clip using both open and fetoscopic techniques. The tracheal occlusion group required an EXIT procedure to remove the clip at birth. In this small study, we found that fetoscopic tracheal occlusion in severe CDH conferred a survival advantage compared to open tracheal occlusion or standard postnatal therapy.[25] In 2003, the National Institutes of Health (NIH) sponsored a trial comparing fetoscopic tracheal occlusion with a clip to standard postnatal care in fetuses with severe CDH. Results of the trial showed survival of 75% with no difference between the tracheal occlusion group and the standard postnatal care group.[26] The survival in the postnatal care group was considerably greater than historical controls. Although this study did not demonstrate a difference in survival between the prenatal intervention group and the postnatal one, the results of this trial demonstrate the tremendous importance of proper randomized controlled trials for novel fetal surgical procedures.

Refinement of tracheal occlusion techniques has progressed from tracheal clipping to percutaneous, fetoscopic placement and retrieval of a detachable, intratracheal balloon. In utero retrieval of the balloon obviates the need for an EXIT procedure. Further data regarding tracheal occlusion suggest that short-term reversible tracheal occlusion may be preferable to longer-duration occlusion. Animal models of tracheal occlusion have demonstrated the benefits of short-term, reversible tracheal occlusion on fetal lung growth. Furthermore, long-term tracheal occlusion has been shown to be deleterious to type II pneumocytes: the cells that secrete surfactant.[27] In Europe, temporary fetal tracheal occlusion for CDH has been associated with survival of 50%. However, the unusually low survival of 15% in the standard therapy group has called the quality of postnatal care into question.[28] A prospective randomized trial of temporary tracheal occlusion versus standard therapy is underway in Europe, while safety and feasibility testing of the device is ongoing in the United States. Our group currently offers reversible, fetal tracheal occlusion for fetuses with liver herniation in the chest and an LHR of less than 1.0, as these patients continue to have greater than 60% mortality. We perform the initial procedure between 24 and 26 weeks gestation and remove the balloon between 32 and 34 weeks.

Tumors

Fetal tumors are rare and generally benign. When they do occur, most are best treated postnatally. However, very large tumors can impede venous return to the heart or create high-output heart failure via arteriovenous shunts that can lead to nonimmune hydrops in the fetus. Hydropic changes include polyhydramnios, placentomegaly, fetal skin and scalp edema, and pleural, pericardial, and peritoneal fluid accumulation. Left untreated, fetal hydrops is nearly always fatal; thus, the tumor must be addressed in utero.[29]

Congenital pulmonary airway malformation

Congenital pulmonary airway malformation (CPAM), previously referred to as congenital cystic adenomatoid malformation (CCAM), is characterized by an overgrowth of respiratory bronchioles with associated cyst formation.[30] Although most CPAMs can be managed postnatally, very large CPAMs can result in fetal hydrops and fetal demise. It is known that the size of the CPAM is the most important risk factor for developing fetal hydrops.[31] The most accepted method of predicting fetal hydrops is measurement of the CPAM volume ratio (CVR), defined as the product of the three longest measurements of the lesion on ultrasound, multiplied by the constant 0.52, divided by the head

circumference. Crombleholme et al.[32] demonstrated that a CVR of 1.6 or greater is associated with an increased likelihood of hydrops.

CPAMs that are predominantly microcystic have a more predictable course than the macrocystic CPAMs. Microcystic CPAMs undergo steady growth and then plateau at 26–28 weeks gestation. In contrast, macrocystic CPAMs can abruptly enlarge due to rapid fluid accumulation within the cyst. For these reasons, patients with microcystic CCAMs are followed closely until 26–28 weeks gestation, and then the interval between ultrasound examinations can be lengthened, whereas macrocystic CPAMs require close follow-up throughout the duration of the pregnancy.[31,33]

Management of prenatally diagnosed CPAMs continues to evolve. A fetus of viable gestational age affected with a CPAM and associated hydrops should be delivered and undergo resection in the newborn period. In instances where a dominant macrocystic lesion is present in a previable fetus, thoracoamniotic shunt may reverse the hydrops fetalis.[34] Needle drainage is ineffective, as rapid reaccumulation of fluid is the norm. Fetal pulmonary lobectomy for microcystic CPAM with associated hydrops has been shown to reverse fetal hydrops but is associated with preterm labor and prematurity.[35] Interestingly, hydropic fetuses with large microcystic CPAMs can be successfully treated with administration of maternal steroids. This finding was discovered serendipitously at UCSF after several hydropic fetuses were treated with maternal steroids to enhance fetal lung maturity in preparation for fetal lung lobectomy. Subsequent fetal ultrasounds demonstrated resolution of the hydrops.[36] Several prospective studies have confirmed the effectiveness of maternal steroids for the fetal treatment of large microcystic CPAMs.[37] Macrocystic CPAMs do not respond to steroids and are still best managed with thoracoamniotic shunt placement or fetal surgery when fetuses develop hydrops (Figure 26.3).

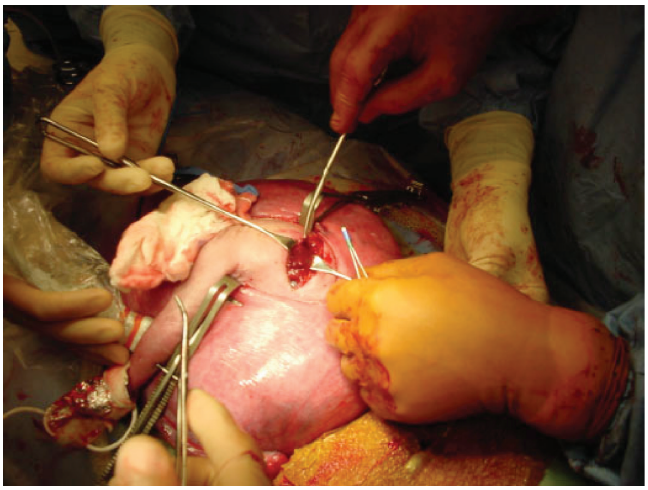

Figure 26.3 Fetal thoracotomy for CPAM. Note that only the right chest and arm are exposed for thoracotomy and pulse oximetry, while the remainder of the fetus is within the uterus.

Sacrococcygeal teratoma

Sacrococcygeal teratoma (SCT) is a rare tumor that is increasingly diagnosed in utero, allowing for greater understanding of the prenatal natural history of the disease. As with CPAM, fetuses with SCT can develop hydrops and in utero demise. SCT tumors can grow rapidly to a tremendous size in relation to the fetus, resulting in a vascular shunt and, in the extreme form, high-output cardiac failure and nonimmune hydrops. Rarely, tumors bleed either into the tumor or externally and can cause fetal anemia and hypovolemia. Other potential problems with a fetus with a large SCT are dystocia and preterm labor. Delivery can be particularly difficult when the diagnosis has not been made prenatally. Traumatic delivery may result in hemorrhage or tumor rupture. Most clinicians would favor cesarean delivery for fetuses with large SCTs. Thus, prenatal diagnosis and careful obstetrical planning are critical in the appropriate management of the fetus with an SCT.

Tumor morphology and tumor vascularity,[38] tumor growth rate,[39] and tumor metrics such as tumor volume–to–fetal weight ratio (TFR)[40] have all been defined as predictors of poor outcomes. The best predictors of risk for fetal hydrops and poor outcomes are solid tumor morphology and TFR >0.12.[40] Fetal resection of SCT in the face of hydrops reverses the pathophysiology if it is performed before mirror syndrome (maternal eclampsia) develops in the mother.

Among 15 fetuses with SCT and hydrops treated at UCSF, five survived (33%), five died in the neonatal period, and five died in utero. The most common method of fetal intervention is hysterotomy with resection or debulking of the tumor.[40] A predominantly cystic lesion may be amenable to percutaneous drainage or placement of a shunt. Attempts at ablating the tumor, either through alcohol injection or RFA, have been met with mixed success.[41]

ABNORMALITIES OF TWIN GESTATIONS

Identical twins may have separate placentas (dichorionic) or share a single placenta (monochorionic). Monochorionic twins may have unequal shares of placenta or blood flow and are at risk of discordant growth. More severe anomalies such as twin–twin transfusion syndrome (TTTS) or twin reversed arterial perfusion sequence (TRAP) can arise from monochorionic pregnancies. Complications arising from monochorionic twin gestations are the most common cause for referral to fetal diagnosis and treatment centers.[42]

Twin–twin transfusion syndrome

In monochorionic twins, there are connections on the placental surface between the umbilical arteries and veins arising from each twin. Normally, the blood flow between the twins is relatively balanced. TTTS occurs when there is net

flow from one twin to the other. TTTS complicates about 10% of monochorionic pregnancies.[42] As a result of the transfusion of blood from the "donor" twin to the "recipient" twin, hemodynamic compromise can occur in either or both twins. The donor twin suffers from a low flow state and can sustain injuries to the brain and kidneys. Conversely, the recipient twin has fluid overload and can develop high-output heart failure and hydrops. The hallmark of TTTS is oligohydramnios in the donor twin and polyhydramnios in the recipient. In addition, often there is size discordance between the twins, with the donor being smaller than the recipient. Advanced disease is evidenced by progressive discordance in fluid volumes, with the donor becoming "stuck" in its amniotic sac due to a complete lack of fluid. In addition, worsening cardiac changes in the recipient portend a grave prognosis. If left untreated, TTTS carries 80%–90% mortality for both twins. In addition, if one twin dies, the other twin is at risk for neurologic injury due to a sump phenomenon in the placenta and demised fetus and from embolism.[43]

Previously, standard therapy for TTTS was serial high-volume amnioreduction of the polydraminiotic sac with the aim of decreasing the risk of preterm labor. The International Amnioreduction Registry showed that amnioreduction resulted in survival of 58%. However, survivors of TTTS treated with amnioreduction had an 18%–26% incidence of significant neurologic and cardiac morbidity. Additionally, serial amnioreduction does not confer a survival benefit in severe cases of TTTS.[44]

Fetoscopic laser photocoagulation of intertwin vascular connections has emerged as the gold standard for TTTS. This can be done nonselectively by ablating all inter-twin connections, or selectively, by ablating only Arterial-Venous (AV) connections with flow in the causative direction. Fetoscopic laser ablation is generally performed percutaneously using a 3–4 mm fetoscope with a side channel for irrigation and introduction of the laser. A large European prospective trial compared amnioreduction to selective laser ablation of intertwin vessels for the treatment of severe TTTS. The main outcome variable was survival of at least one twin. The trial was stopped early after interim analysis showed a clear survival advantage to laser therapy: 76% versus 51% for single survivor and 36% versus 26% for dual survivor.[45]

Twin reversed arterial perfusion

TRAP is a rare disease of monochorionic twins that occurs when one normal twin acts as a "pump" for an acardiac, acephalic one. As the acardiac, acephalic twin grows, the normal pump twin goes into high-output cardiac failure and hydrops. The blood flow in the acardiac twin is characteristically reversed, and thus, the acronym *TRAP* was coined to describe this anomaly. The natural history of TRAP is greater than 50% mortality in the pump twin due to hydrops.[46] The risk of hydrops increases as the mass of the acardiac twin increases relative to the normal twin. Generally, we choose to intervene when there is evidence of hydrops in the pump twin, or when the estimated fetal weight of the acardiac twin is 50% or more relative to the pump one.

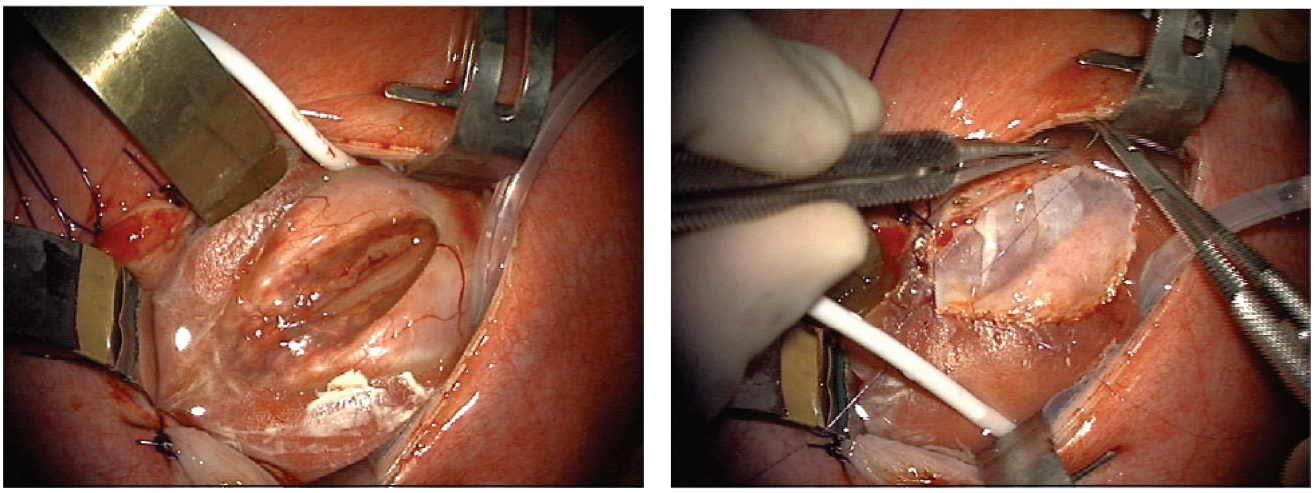
Multiple techniques have been used to separate the vascular supplies in TRAP pregnancies: open hysterotomy and delivery, fetoscopic ligation, bipolar cautery, harmonic scalpel division, thermal coagulation, and laser coagulation.[47] At UCSF, an RFA device is introduced percutaneously under ultrasound guidance to coagulate the umbilical cord insertion site on the acardiac twin's abdomen. RFA of TRAP pregnancies between 18 and 24 weeks gestation resulted in 92% survival with delivery at a mean gestational age of 36 weeks.[48]

Myelomeningocele

MMC, or spina bifida, is characterized by an open neural tube and exposed spinal canal elements. MMC can occur anywhere along the spine but most commonly occurs in the lumbar or cervical vertebral levels. Complications include neurologic deficits with motor and somatosensory abnormalities. In addition, bowel and bladder function is often deranged due to injury to the autonomic nervous system. Finally, nearly all patients with MMC develop the Arnold–Chiari II malformation of the hindbrain that results in noncommunicating hydrocephalus, and most will require ventriculoperitoneal (VP) shunting. Unlike previous patients considered for fetal intervention, fetuses with MMC have low perinatal mortality. Despite postnatal repair of the defect, the attendant morbidity from neurologic abnormalities is severe, and up to 30% of patients die before reaching adulthood.[49]

The rationale for fetal intervention in MMC is the "two-hit" hypothesis, where the first hit is the original neural tube defect that results in the open spinal canal. The second hit is postulated to be due to direct trauma to the exposed neural elements while the fetus is in utero.[50,51] It is this second hit that could potentially be ameliorated by fetal surgery. Animal models for fetal MMC proved this hypothesis and showed that in utero repair of the MMC improved distal neurologic function and reversed the Arnold–Chiari II malformation.[52]

These animal data led to pilot studies in human fetuses. MMC is the first nonlethal anomaly for which fetal surgery was undertaken (Figure 26.4).[53] Early attempts at fetal MMC repair showed promise in reversing the Arnold–Chiari II malformation and possibly decreasing the need for VP shunting.[54] The NIH sponsored a multicenter randomized trial (Management of Myelomeningocele Study [MOMS]) comparing fetal MMC repair at 19–26 weeks gestation versus postnatal repair. The success of the trial depended on the cooperation of all fetal centers in the country to place a moratorium on fetal MMC repair outside the context of the trial. The objectives of the trial were (1) to determine if fetal MMC repair improved survival or need for VP shunt by 1 year of life compared to standard postnatal repair and (2) to determine if fetal MMC repair improves motor and



(a) (b)

cognitive function at 30 months of age compared to postnatal repair. The study closed early because of the superiority of fetal surgery. Fetal MMC repair reduced the need for ventricular shunting for hydrocephalus at 1 year (fetal group: 40% vs. postnatal group: 82%, $p < .001$) and improved motor function, including the ability to walk at 30 months of age (fetal group: 42% vs. postnatal group: 21%, $p < .01$). Fetuses treated prenatally were born at an average gestational age of 34.1 weeks, and 13% were born before 30 weeks gestation.[55]

THE FUTURE

The requirements for intervention to correct a fetal defect remain the same:

1. Experimental work to prove the pathophysiology of the defect
2. Careful study of the natural history of the untreated disease
3. Ability to select the fetus that will benefit from prenatal treatment

Stem cells and gene therapy

Gene therapy for prenatally identifiable diseases is currently experimental and is being actively pursued for specific disorders. In utero treatment with stem cells and/or virally directed genes may halt the progression of disease during gestation. The fetal immune system develops gradually, and prior to 15 weeks gestation, the fetus is in a preimmune state. Thus. in utero transplantation may avoid problems with rejection and graft-versus-host disease that are seen with postnatal transplantation.

Specific issues for in utero treatment of genetic diseases include timing of diagnosis, timing of therapy, delivery of stem cells or genes, sources for stem cells, and durability of treatment. With the advent of chorionic villus sampling, genetic diseases can be identified in the first trimester. Timing of potential treatments is crucial in order to take advantage of the possible preimmune status of the fetus, making fetuses potentially more receptive to exogenous genes or cells.[56] Several investigators have utilized hematopoietic stem cells (HSCs) as a vector to attempt to induce chimerism in order to treat the disease. Others have investigated the use of retroviral vectors in order to insert genetic material into fetal animals. This approach reduces the problem of obtaining the large numbers of stem cells needed to create even a modest amount of chimerism. Other approaches include use of maternal stem cells or genetic material as studies have demonstrated early cross-trafficking of maternal cells in the fetus. Candidate diseases include hematologic, immunologic, metabolic, and neurologic abnormalities.[57] To date, the only durable in utero HSC has been for severe combined immunodeficiency syndrome. Currently, in utero gene therapy and stem cell therapy are in their infancy but remain active topics of research and investigation.[58]

SUMMARY

Fetal surgery has progressed from an investigational therapy to an accepted mode of therapy for selected fetal diseases. The progress seen in the field of fetal surgery is a testament to the power of a rigorous investigational process, i.e., identifying clinical needs, understanding of the pathophysiology in the laboratory, the documentation of the natural history in the human fetus, and the push for less and less invasive procedures. Through these efforts, diseases with historically high perinatal mortality rates have shown improved survival with fetal surgery. Furthermore, NIH-funded, prospective trials

have confirmed the value of fetal surgery for diseases such as TTTS and MMC and shown where fetal surgery remains investigational, as is the case for CDH. New areas of research include tissue engineering, stem cell therapy, and gene therapy. As always, maternal safety must remain paramount, and risk to the mother should be minimized at all times.

Many people have contributed to the development and success of fetal treatment and diagnosis. Collaborative, multidisciplinary teams are critical for the success of any fetal treatment program. It is also important to acknowledge the significant contributions of patients and their families to this enterprise. The brave families who chose to undergo early fetal therapies are the true pioneers on whose shoulders the success of fetal treatment rests.

Tissue engineering and stem cell research

PAOLO DE COPPI

INTRODUCTION

Congenital and acquired surgical conditions represent a major cause of morbidity and mortality during the first years of life and childhood. In those complex conditions, prosthetic materials are used because of the lack of biocompatible tissues able to replace or regenerate damaged organs. Besides the risk of infection, the major drawback of using a prosthetic patch closure is the risk of dislodgment and subsequent recurrence of the initial problem. Moreover, foreign body reactions and implant rejection occur when synthetic polymers are used. Regeneration of natural tissue from living cells to restore damaged tissues and organs is the main purpose of regenerative medicine. This relatively new field has emerged by the combination of tissue engineering and cell transplantation as a possible strategy for the replacement of damaged organs or tissues. So far, most of the attention has been focused on degenerative diseases such as Parkinson's or Alzheimer's, while very little has been done for the treatment of congenital conditions. However, the knowledge acquired in the last years from stem cell (SC) biology and regenerative medicine strategies could lead to new ways of repairing or replacing injured organs and systems, even during fetal development, and therefore, pediatric patients could largely benefit from the evolution of this new exciting field. In order to give rise to a new functional organ-like structure, several variables, such as local environment, nutrients, and metabolites, are pivotal. These variables, in the context of tissue engineering, are mainly dependent on the provision of a three-dimensional growth structure termed "scaffold."[1] Scaffolds can be either natural of synthetic. Natural scaffolds are essentially bioactive but lack mechanical strength. Synthetic scaffolds lack bioactivity, are mechanically strong and can be engineered with bespoke macrostructure and microstructure, which has the potential to enhance cellular growth and organogenesis.[2] Scaffolds could ultimately represent the exclusive tool required for tissue engineering, and several attempts to generate whole organs such as liver have been conducted using structures with vascular channels to ensure an adequate network of vascular supply.[3] Major developments in regenerative medicine have been achieved following the discovery of cells which can be isolated and expanded in number outside the body. SCs are unspecialized cells with the capacity to both self-renew, and give rise to multiple mature specialized cell types through asymmetric cell division.[4] There are three main sources of SCs in humans and animals: embryonic, fetal, and adult tissue. Adult SCs have a limited cellular regeneration, or turnover, this could represent a limitation for tissue engineering applications, where a large number of cells are necessary.[5] SCs they can be identified in many adult mammalian tissues, such as bone marrow (BM), skeletal muscle, skin, and adipose tissue, where they contribute to the replenishment of cells lost through normal cellular senescence or injury.[6–10] In contrast, SCs derived from embryonic sources have the ability to give rise to cells that not only proliferate and replace themselves indefinitely, but also have the potential to form any cell type.[11,12] Embryonic stem (ES) cells are derived from the inner cell mass of pre-implantation embryo, they are pluripotent, and demonstrate germ-line transmission in experimentally produced chimeras.[13,14] More recently, cells with intermediate potency have derived from the amniotic fluid (fetal SCs)[15] and from adult SCs which have been reprogrammed using various factors implicated in the maintenance of pluripotency in ES cells.[16] This chapter would like to offer an insight on the latest evolution of SCs, with a glance at their possible application for regenerative medicine, and recent clinical translations, particularly in the pediatric surgery field.

STEM CELLS

ES cells

ES cells derive from the inner cell mass of a blastocyst stage embryo.[17] They are pluripotent and give rise during development to all derivatives of the three primary germ layers: ectoderm, endoderm, and mesoderm; hence, they

possess the potential to develop into most cell types within the body.[13,18,19] The field of ES cell research began with the study of teratocarcinoma cells in the 1950s, and continued in 1981 with first mouse ES cell lines derived from the inner cell mass of blastocysts using culture conditions (fibroblast feeder layers and serum). The field progressed further in 1998 when Thomson et al.[13,20,21] first isolated human ES (hES) cells. Optimal culture conditions have been developed for both mouse ES (mES) and hES cells to evaluate and maintain both their proliferative and differentiative capacities. mES cells are grown on a layer of gelatin and require the presence of leukemia inhibitory factor, while hES cells are grown on a feeder layer of mouse embryonic fibroblasts and require the presence of basic fibroblast growth factor.[18] The maintenance of pluripotency in the hES is assured by the presence of different transcription factors like Oct-4, Nanog, and SOX2, which are essential to ensure the suppression of genes that lead to differentiation.[22] The cell surface antigens most commonly used to identify hES cells are the glycolipids stem cells embryonic antigen-3 and -4 (SSEA3 and SSEA4) and the keratan sulfate antigens Tra-1-60 and Tra-1-81.[9] ES cells can be used to generate tissues but could also be employed as "cellular models" to study a range of human diseases, and to test new drug candidates for efficacy and toxicity (Figure 27.1).[23] ES cells, being pluripotent, require specific signals for correct differentiation, and if injected in vivo prior to commitment, they will give rise to many different types of cells, resulting in the formation of teratomas. So far, their potency, together with the difficulties related to their allogenic origin, have limited their possible clinical application.[24] In particular, the political debate surrounding SC research began suddenly after hES were created from a human embryo which was subsequently destroyed. Recently, researchers opened the possibility of generating ES cell lines without destroying embryos, by deriving cells from earlier stages of embryo development, and without impairing future development of the embryo.[25–27] Moreover, in the last few years, ES cells have been used as a model for tissue differentiation, and rudimental organs derived from ES cells have been engineered. Understanding the signaling necessary for terminal differentiation has been important in defining the lineage-specific transcription factors, which can potentially be used to genetically engineer and terminally differentiate pluripotent SCs, increasing the chance of producing functionally differentiated tissues.

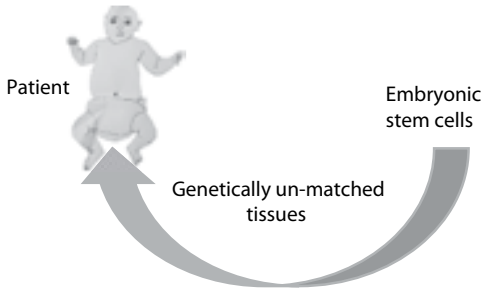

Figure 27.1 ES cells can be derived from culturing of fertilized eggs and differentiated into mature specialized tissues, which are, however, not matched to the recipient, and therefore ES cell transplantation must be associated to immunosuppression.

Somatic cell nuclear transfer

Somatic cell nuclear transfer (SCNT) has also been adopted to create patient-specific SCs, and avoid problems relating to the creation of allogenic tissue. This procedure specifically entails the removal of an oocyte nucleus in culture, followed by its replacement with a nucleus derived from a somatic cell obtained from a patient. SCNT technique was first reported by Briggs and King[28] and some years after was used to obtain the first vertebrate (a frog).[29] Cells yielded by this process are genetically identical to the donor and would not be rejected by the patient. SCNT can potentially be used for three purposes: (1) reproduction, leading to generation of an embryo for continuation of life (a notable example in 1996 was the generation of the first mammal, a sheep named Dolly, derived from an adult somatic cell using this technique[30]); (2) therapy, generating blastocysts for SC derivation; and (3) research and regenerative medicine. The first is scientifically and ethically condemned. The second has important implications for the future of ES therapies, allowing the production of nonimmunogenic ES lines. Besides, this cells could be stored and used subsequently for the treatment of future medical conditions. As a consequence, this could be relevant to the creation of autologous tissues for use in children who are born with complex malformations, in which tissue viability represents a problem and where patient-specific cells could be created *in vitro*. ES cells derived using SCNT would have the same genetic background as the patient who donated the initial genetic material, and the tissue created would not be rejected after transplantation. ES cells have, in fact, the advantage of being extremely plastic, facilitating the *in vitro* engineering of complex organs such as heart, liver, and kidney.[31–33] Nevertheless, in spite of the ethical considerations, the limitation of this technique is related both to the low efficiency, leading to a high loss in cell yield, and the inadequate supply of human oocytes.[34]

Induced pluripotent SCs

Since the major objection to hES research is their immunogenicity, it would be advantageous to develop a method of creating SCs from autologous tissue. Generation of induced pluripotent stem (iPS) cells, described by Yamanaka et al. in 2006, avoids both the immunological and ethical problems (Figure 27.2). iPS cells can be developed from nonpluripotent cells, usually adult somatic cells, by causing a forced expression of several genetic sequences such as Oct4 (POU5F1), the transcription factor Sox2, c-Myc proto-oncogene protein, and Klf4 (Krueppel-like factor 4). In 2007, successful iPS cells were obtained from human

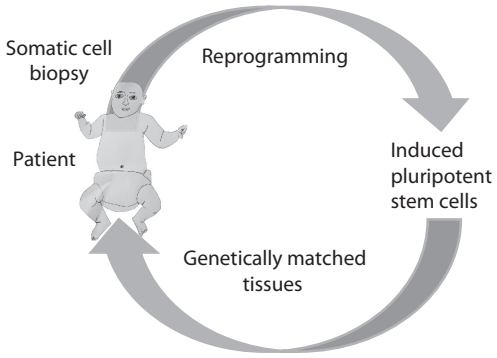

Figure 27.2 iPS cells can now be obtained from adult cells by reprogramming. It creates genetically matched tissues, but genetic manipulation of the cells during reprogramming can be teratogenic.

fibroblasts both using Oct3/4, Sox2, Klf4, and c-Myc with a retroviral transfection, and using OCT4, SOX2, NANOG, and a different gene LIN28 using a lentiviral system, improving transduction output.[36,37] The viral transfection systems used to insert the genes at random locations in the host's genome created concern for potential therapeutic applications of these iPS cells, because it might increase the risk of tumor formation.[38] To overcome these dangers, some studies have used adenovirus to transport the four sequences into the DNA of mouse somatic cells. Since the adenovirus does not combine any of its own genes with the targeted host, the danger of creating tumors is eliminated.[39] Yamanaka et al. have since demonstrated that reprogramming can be accomplished via plasmids without any virus transfection system at all, although at very low efficiencies.[38] iPS cells show morphological resemblance to hES cells, express typical human ES cell-specific cell surface antigens and genes, give rise to multiple lineages *in vitro*, and form teratomas when injected into immunocompromised mice. The efficiency of reprogramming adult fibroblasts has been low (<0.1%). However, since reprogrammed clones could consistently be recovered and expanded with existing gene combinations, for practical applications, the low reprogramming efficiency itself was not really considered an issue, unless reprogramming selects abnormal genetic or epigenetic events that were stably propagated in the resulting iPS cell lines.[40] Recently, Jaenisch's group found an elegant way to derive iPS from somatic cells of patients, free from reprogramming factors using Cre-recombinase excisable lentiviruses. The efficiency of reprogrammed iPS is very high with a low number of proviral vector integrations, and the cells maintain a gene expression profile more similar to hES than to hiPS these cells have been subsequently differentiated into dopaminergic neurons, demonstrating that Parkinson's disease patient-derived iPS cells can be free of viral reprogramming factors.[41] Interestingly, in the surgical community, the possibility to derive and isolate enteric nervous system (ENS) progenitors from human pluripotent SCs, and their further differentiation into functional enteric neurons, has been recently demonstrated.[42] ENS precursors derived *in vitro* are capable of targeted migration in the developing chick embryo and extensive colonization of the adult mouse colon.[43] Moreover, iPS cells can be generated from fetal cells without any genetic manipulation. We have recently described that iPS cells can be easily derived from first trimester amniotic SCs when grown on Matrigel in hES cell medium, supplemented with the histone deacetylase inhibitor valproic acid.[44] It is possible that, because of their fetal origin, amniotic fluid stem cells (AFSC) (discussed in detail later) could be ideal for cell banking of patient-specific pluripotent cells and possible applications in pharmaceutical screening.

Fetal SCs

Fetal cells may represent the ideal source for therapy (Figure 27.2). Like ES cells, they are still plastic and easy to expand, and, in common with their adult counterparts, they are less controversial, not tumorigenic, and can be developed in an autologous setting. The latter is particularly important in the context of congenital malformation, as surgical treatment is often complicated by insufficient available tissue at time of repair. Regularly, artificial materials have been the only option for reconstruction in such cases, with high rates of morbidity. Recently, fetal tissue engineering has emerged as a promising concept in surgical reconstruction of birth defects. Redundant or purposely obtained fetal cells could be harvested, cultured, and manipulated *in vitro* during the remainder of pregnancy, and used later for tissue engineering of graft material that will be applied in postnatal reconstruction. Indeed, in the case of prenatal diagnosis of structural defects, there is the possibility of obtaining homologous cells at the time of invasive sampling such as chorionic villi biopsy, cordocentesis, or amniocentesis. Sampling of amniotic fluid is ideal for prenatal/neonatal applications with the following advantages: (i) relatively easy to perform, (ii) low risk for both the mother and the fetus, and (iii) a widely accepted method of prenatal diagnosis. AFSC's represent about 1% of all whole cells in cultures of human amniocentesis specimens, obtained for prenatal genetic diagnosis, these cells can be purified by immunoselection using c-Kit (CD117).[41] AFSC's are described as broadly multipotent SCs that can differentiate into adipogenic, osteogenic, myogenic, endothelial, neurogenic, and hepatogenic lineages, inclusive of all embryonic germ layers (Figures 27.3 and 27.4).[15,45–50] In contrast with mesenchymal cells, AFSC's show hematopoietic engraftment[51] and a functional and stable integration into the skeletal muscle SC niche, highlighting their value as the cell source for the treatment of muscular pathologies and skeletal muscle defects.[52] This group of cells can be steadily expanded in cultures without a feeder layer and has a typical doubling time of 36 hours. Subconfluent cells show no evidence of spontaneous differentiation; nevertheless, under specific inducing conditions, these cells are able to differentiate and, if injected *in vivo*, show no evidence of tumor growth in severe combined immunodeficient

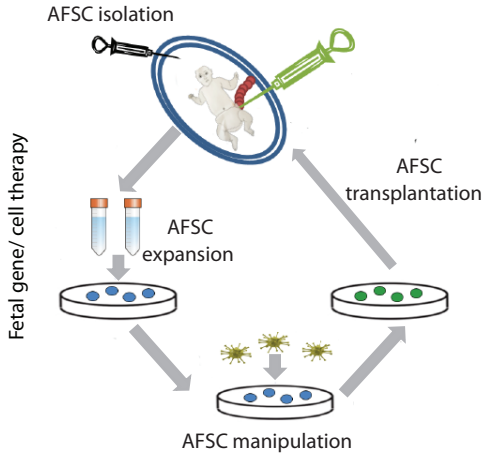

Figure 27.3 AFSC's can be used for *in utero* cell or cell/gene therapy in the same individual and therefore overcome the immunological problems, and they have higher potential than adult SCs.

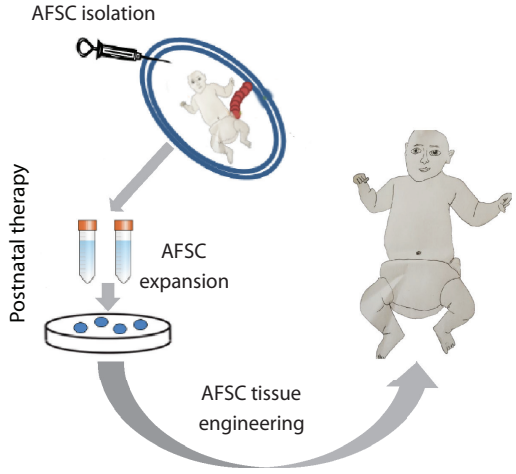

Figure 27.4 AFSC's can be used for engineering autologous tissue for postnatal transplantation and therefore overcome the immunological problems, and they have higher potential than adult SCs.

mice. AFSC's are positive for a number of surface markers commonly expressed by mesenchymal SCs (MSCs), but not by ES cells, such as CD29, CD44 (hyaluronan receptor), CD73, CD90, and CD105 (endoglin).[53] Human AFSC's are also positive for stage-specific embryonic antigen (SSEA)-4 which is expressed by previously used ES cells, and >90% of the cells express the transcription factor Oct4, which has been associated with the maintenance of the undifferentiated state and the pluripotency of ES and embryonic germ (EG) cells.[15,54] First trimester AFSC's can also be fully reprogrammed without using any genetic manipulation.[44] AFSC's can be used as a carrier for congenital monogenic disease, which theoretically could be corrected by a combined-approach gene-cell therapy (Figure 27.3). Following this approach, AFSC's could be isolated, the defect identified and corrected, and the cells injected back to the donor avoiding both fetal and maternal immunorejection. Alternatively, in cases of structural anomalies, AFSC's could be expanded and used to engineer the missing tissue/organ (Figure 27.4). MSCs derived from amniotic fluid have already been used in large animal models for the repair of surgically created diaphragmatic defects,[55] and engineered diaphragmatic tendon graft using mesenchymal amniocites has obtained preclinical validation and may soon become a clinical reality.[56]

Adult SCs

At the farthest end of the spectrum, we have SCs that are present in the postnatal life, are more differentiated/mature, and are classified as either multipotent or unipotent (Figure 27.5). Classically, hematopoietic SCs (HSCs) have successfully been used for more than 25 years, and transplantation of BM and cord blood (CB) HSCs is routinely performed for hematological/oncological disorders. Following preliminary studies by Friedenstein et al.,[57] other cells, defined as MSCs, distinguishable from HSCs because of the capacity to grow in adherent culture, were described. MSCs are multipotent SCs with fibroblast-like morphology, which can differentiate into osteogenic (bone), chondrogenic (cartilage), and adipogenic (BM stroma) lineages *in vitro*.[6,58] Their existence was first hypothesized when tissues biopsied (skeletal muscle, skin, heart, and even brain) from patients, who previously received a BM transplant, showed donor cell engraftment. To date, MSCs have been isolated both in the fetus and postnatally from blood, liver, and BM, amniotic fluid, lung, pancreas, dental pulp, and periosteum.[59–64] They have also been isolated from umbilical CB, Wharton's jelly, and placenta. These parts, previously considered a "biological waste," today are among the most interesting for MSC isolation.[65–67] Three major criteria to define MSCs have been introduced by the International Society for Cell Therapy[68]: (i) the cells must be plastic-adherent when maintained under standard culture conditions; (ii) >95% of the MSC population must express CD73 (ecto 5'-nucleotidase), CD90 (Thy-1), and CD105 (SH2 or MCAM or endoglin), LNGFR (low-affinity nerve growth factor receptor), CD166, ALCAM adhesion protein, CD146 (P1H12), CD29, and CD106 (vascular

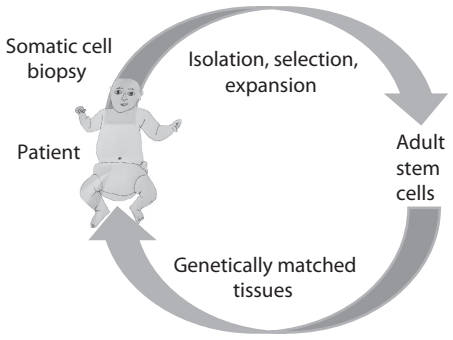

Figure 27.5 Adult SCs are relatively safer to use clinically, but they are limited in expansion and differentiation.

adhesion molecule-1 [VCAM-1]), and >98% MSC should be negative for hematopoietic cell surface antigens: CD45, a pan-leukocyte marker; CD34, a marker of primitive hematopoietic progenitors and endothelial cells; either CD11b or CD14, markers for monocytes; either CD19 or CD79a, B-cell markers; and human leukocyte antigen (HLA class 2); and (iii) MSC should be capable of differentiating into osteoblasts, chondroblasts, and adipocytes when placed into an appropriate induction/differentiation medium. Adult SCs or progenitors have already been used clinically to engineer urological constructs such as bladders and urethras, blood vessels, cornea, esophageal epithelium, bronchi, and tracheas. Moreover, MSCs have been tested for cellular therapy in pediatric patients for several clinical indications, such as inborn errors of metabolism (metachromatic leukodystrophy, Hurler syndrome, infantile hypophosphatasemia), osteogenesis imperfecta, and GVHD.[69–73] However, in contrast with the aforementioned cells, MSCs also have a limited lifespan and become senescent when cultured *in vitro*. This is a major problem for therapy since, regardless of the isolation procedure, the MSC quantity obtained from primary tissues is not sufficient for any downstream MSC application in clinical settings. *In vitro* expansion can affect biological properties of the cells, and MSCs go through very significant changes in phenotype and gene expression as a result of cell culture adaptation. Although considered a safer source compared with ES cells, the prospective clinical applications of MSCs require meticulous examination (Figure 27.5).

SCAFFOLDS

In order to develop a tissue-engineered construct to replace missing or damaged tissue, the combination of appropriate cellular engineering and material science is needed. Material science is concerned with the production of acellular scaffolds that can be seeded with cells, allowing and promoting their growth. General attributes that a scaffold must fulfill include

(i) Biocompatibility that does not lead to an immunogenic response from the host
(ii) Biodegradation in a suitable time period that permits sufficient cellular growth while not producing harmful degradation products
(iii) Mechanical properties that are in line with tissue growth; a significant amount of three-dimensional support in the early stages without obstructing cellular extracellular matrix production in the later stages

More specific scaffold attributes are related to the aim of recreating the nonmechanical attributes of the ECM. These properties include the mediation of cell adhesion via integrin receptors,[74] as well as positive influence on cell survival and proliferation by means of growth factors and cytokines.[75] What is more, the ECM has been argued to be involved in mechanochemical transduction, as shown by the differentiation of MSCs to neurons, muscle cells, and osteoblasts when seeded on a substrate mimicking the elasticity of each of those host tissues respectively.[76]

Materials used, thus far, for tissue engineering have been traditionally divided into three categories: (i) naturally derived materials (e.g., collagen and elastin), (ii) synthetic materials (e.g., poly(L)-lactic acid [PLA], polyglycolic acid [PGA], and polylactic-co-glycolic acid [PLGA]), and (iii) natural acellular scaffolds.

Naturally derived materials

Materials composed of naturally occurring macromolecules, in particular those that formulate the ECM, have been tested for tissue engineering purposes. They have the advantage of having a specific structure with which cellular integrins bind well, promoting cellular adhesion. A classic example is collagen, the most abundant protein found in the ECM, making up a quarter of the total protein content in many animals.[77] So far, there have been 29 different types of collagen identified, though 90% of the collagen in the body are types I, II, III, and IV. In vertebrates, approximately 22% of the total protein content is of collagen type I, and in vascular tissue, such as the aorta, 80%–90% of the collagen content is of type I or III[2]. Collagen extracted from animal and human tissues has been used due to its influence in cell adhesion and proliferation[78] as well as low inflammatory and immunogenic responses.[79] Mechanical properties of the collagen-based scaffolds, including resorption rate, may be altered according to porosity, fiber orientation, and cross-linking conditions. Commercially available collagen has, for example, been cross-linked with 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDC) and N-hydroxysulfosuccinimide (NHS) and gellated on a nanopatterned polydimethylsiloxane (PDMS) surface.[80,81] Elastin is another ECM protein and is mainly found in blood vessels, making up a large part of the ECM content of arteries. It provides the arteries with their elastic properties and also has antithrombogenic properties.[82] Elastin scaffolds have developed using recombinant human elastin grown in *Escherichia coli* and then purified.[83,84] In order to optimize the environment, multiple ECM elements can be combined. For example, in vascular tissue engineering, production of a tubular scaffold containing both collagen and elastin allowed smooth muscle cells (SMCs) to orientate themselves in line with the fibers.[85–87]

Synthetic materials

Synthetic materials were considered as a possibility for tissue engineering following their use as biomaterials in other areas of medicine. They are advantageous because (i) they are easily cheaply manufactured, (ii) they can be formed into various shapes with the required dimensions (the microstructure and nanostructure can be well controlled), and (iii) they can be produced with a range of different mechanical

properties and (iv) manufactured reproducibly. For all these reasons, synthetic polymers should be the best choice for clinical translation; however, it has been clearly very difficult to replicate in a laboratory the millions of years that evolution has taken to design the structure and composition of our tissues and organs. Some of those synthetic polymers, such as the polyester polymers, have been firstly used and already employed as sutures and orthopedic fixatives such as pins, rods, and screws.[88] The advantage of those scaffolds is related to scaffold degradation that occurs through hydrolytic attack of the ester bond, and its rate is affected by adjusting various properties of the scaffold including crystallinity, molecular weight, and porosity. The existing wide clinical application of polyesters supports their biocompatibility, although some studies have suggested that there can be problems due to their propensity to disintegrate into small particles[89] or toxicity associated with acidic degradation.[90] A commonly used biodegradable synthetic polymer is polyglycolic acid (PGA). Its degradation product, glycolic acid, is a natural metabolite and can therefore be readily metabolized without toxic effect, and is already in use as a material for resorbable sutures. PGA is a polyester with high crystallinity and as such is a stiff and brittle material.[91] It also has a fast degradation rate of 6 to 8 weeks[92] when fabricated as a mesh. Cao et al.[93] reported a 40% loss of mass over 8 weeks for a PGA mesh in pH 7.4 phosphate buffered saline (PBS) at 37°C and 5% CO_2, when pretreated with NaOH. The same group has cultured SMCs on a PGA mesh in a bioreactor and has seen almost complete loss of PGA after 8 weeks and production of ECM products like collagen.[94] PLA is a semicrystalline polymer with a similar rate of degradation to that of PGA and along with PGA is one of the few biodegradable polymers approved by the Food and Drug Administration for clinical use. It is often used in its L chiral form, PLLA, as this is preferentially metabolized. Lu et al.[95] isolated outgrowth endothelial cells from rabbit peripheral blood and grew them on an electrospun PLLA scaffold, where cells grew preferentially on aligned fibers. Polycaprolactone (PCL) is another semicrystalline polyester but with a much longer degradation time than PLA. As a homopolymer, it has shown degradation times of up to 2 to 3 years.[88] Taking inspiration from the mussel byssus, with its impressive adhesive qualities, that possesses a large number of catechol moieties, the pair posited that introducing catechol moieties via a poly(dopamine) coating would increase cellular attachment.[96] When compared with uncoated and gelatin-coated, the poly(dopamine)-coated PCL showed an increased number of live human umbilical cord endothelial cells (HUVECs) on the surface. Other groups have coated electrospun PCL with collagen,[97] fibroin and chitosan,[98] or PCL films with fibrin-based coating.[99] While electrospinning is still a very popular technique for fabricating PCL[100] and other scaffolds, related methods for creating nanofibers of a similar geometry to ECM fibers are being developed, such as jet-spraying.[101] When large amounts of tissue are to be engineered, vascular supply is an issue with synthetic materials since no means of attachment to the vascular tree can be inherently designed to the scaffold. It is in these cases that mechanical properties such as porosity become important, affecting both cell motility and vascularization.[102]

Natural acellular matrix

Natural acellular matrices are organs from humans or animals that have been treated to remove cells and immunogenic material, producing natural scaffolds that maintain their architecture of origin. Following decellularization, these scaffolds may be implanted with or without prior cell seeding, aimed at regenerating a complete organ or improving tissue repair, respectively. The benefits of this technique include the preservation of the ECM, which favorably influences cell fate, as well as of the macro- and micro-architecture. The macro-architecture is important in recreating the three-dimensional structure of the organ to be tissue-engineered as well as maintaining a vascular tree that will allow for cell and nutrient delivery and waste removal. The micro-architecture is of value toward maintaining the mechanical properties and porosity of the tissue that will be optimal for cell seeding and growth. Since ECM components are preserved across species,[103] immunogenic responses are removed.[104,105] The decellularization process can be performed in a variety of manners including mechanical, chemical, and enzymatic methods. The aim is to remove cellular material while preserving the integrity and constituents of the ECM. Mechanical methods such as snap freezing, direct pressure, and sonication have been reported to disrupt ECM.[106] The major chemical methods used for decellularization include ionic detergents such as sodium dodecyl sulfate (SDS) and sodium deoxycholate, nonionic detergents such as Triton X-100, and zwitterionic detergents such as 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate hydrate (CHAPS). Our experience with intestinal and bladder decellularization has suggested that a combination of milliQ water, sodium deoxycholate, and DNase is superior to the use of Triton X-100 in preserving ECM structure and collagen/glycosaminoglycan (GAG) content while removing cellular material.[105] Comparing the benefits of each method is beyond the scope of this review, and when they are looked at, they should be examined in a tissue-specific manner. They have the added hypothetical advantages over synthetic scaffolds of not producing potentially toxic degradation products or inducing inflammation, characteristics that may be important in the prevention of stenosis.[106] A successful example of natural acellular tissue currently used in the clinic is small intestinal submucosa (SIS) harvested from mammalian small intestine and treated with peracetic acid, followed by antibiotic or radioactive sterilization. Beyond preservation of the ECM structure, GAG, and collagen content, SIS has been demonstrated to contain growth factors such as vascular endothelial growth factor (VEGF),[107] fibroblast growth factor-2 (FGF-2), and tumor growth factor-β (TGF-β).[108] VEGF stimulates angiogenesis of the tissue, whereas TGF-β has immunomodulatory properties, suppressing T-helper response and reducing

inflammatory or immune reactions.[109] Collectively, these properties provide an environment for tissue growth and vascularization while maintaining sufficient mechanical strength until endogenous ECM production occurs. Clinical uses of SIS include various types of hernia repair,[110–112] anal fistula closure,[113] and dural repair.[114] Similar materials that are being examined for clinical use in tissue repair include amniotic membrane tissue, cadaveric fascia, and acellular dermis (which has been used for full-thickness burns since 1995[115]). Decellularized esophageal scaffolds have been used with reportedly good results in both preclinical and clinical studies.[116,117] Significant heterogeneity exists among studies with respect to the type of scaffold, extent of surgery, and species used, which partly explains the range of results reported. Thus, regeneration of the muscularis propria layer is seen to take place in some studies.[118] Badylak et al.[117] laid sheets of SIS onto the raw internal surface of esophagus following endoscopic submucosal resection in five patients with superficial cancers. With a follow-up of 4–24 months, the scaffold promoted physiological remodeling as evidenced by endoscopy and histological characterization following biopsy. Strictures still formed, but only at areas outside those lined by SIS, suggesting possible technical improvements in scaffold delivery. In fact, when SIS was used to completely cover a 3 × 5 cm mucosal defect in the cervical esophagus, there was no stenosis or other complications and endoscopy at 4 weeks demonstrated good integration of the scaffold.[119] Hypothetically, decellularized esophageal tissue should retain the signals, both chemical and structural, that will direct the appropriate migration and differentiation of host cells, in a way that is unlikely to occur with scaffolds originating outside the esophagus, such as SIS. Ozeki et al.[120] compared two methods of decellularization of adult rat esophagus based on deoxycholate and Triton X-100, respectively, and assessed the resultant tissue using routine histology and biocompatibility. Those treated with deoxycholate showed superior mechanical properties, maintenance of the ECM, and a lower DNA content than those treated with Triton X-100. Bhrany et al.[121] found a combination of 0.5% SDS and Triton X-100 to be effective in decellularization, albeit with a loss of tensile strength as measured by burst pressure studies.[121]

Cell-derived ECM scaffolds

Instead of decellularizing blood vessels to obtain vascular ECM for cell seeding, some groups have taken the approach of culturing vascular cells to produce vascular ECM and then decellularizing. The cells can be allo- or xenogenic, and a much greater degree of control can be had over the manufacture, increasing reproducibility. This is an important factor in good manufacture practices (GMP), necessary if one wishes to take a tissue-engineered device from a lab to a clinic. The fibroblasts can produce a large amount of ECM, which autologous seeded SMCs seeded may not be able to do, depending on patient age, history, and site of extraction. The Niklason group at Yale has seeded SMCs from pigs,[122] canines, or humans,[123] onto PGA scaffolds and cultured them in a biomimetic bioreactor for 10 weeks, before decellularizing the scaffold with a detergent treatment. The scaffolds can then be seeded with cells or implanted directly.

TISSUE ENGINEERING

In order to give rise to a new functional organ-like structure, several variables such as local environment, nutrients, and metabolites are pivotal. Major developments in the clinic have been achieved in the last few years using relatively simple scaffolds. Atala et al.[124] presented in 2006 a series of seven children with myelomeningocele, aged 4–19 years, with high-pressure or poorly compliant bladders, who successfully received an engineered bladder tissues. Briefly, after undergoing a bladder biopsy, urothelial and muscle cells were grown and then seeded onto a biodegradable bladder-shaped scaffold made of collagen, or a composite of collagen and PGA. About 7 weeks after the biopsy, the autologous engineered bladder constructs were implanted and wrapped in omentum with good long-term (mean 46 months) results.[124] The same group described in 2011 their experience with five boys who, following trauma, between 2004 and 2007 underwent urethral reconstruction using tubularized urethras seeded with autologous cells that remained functional for up to 6 years.[125] Macchiarini et al.[126] in 2008, using a decellularized human trachea seeded with autologous epithelial and MSC-derived chondrocytes, successfully transplanted a 30-year-old woman with end-stage bronchomalacia. The engineered left bronchus, at 4 months, functioned normally and was free from the risks of rejection. Using a similar approach, we have recently reported the first child who received a stem-cell-based tracheal replacement with a good functional outcome after 2 years of follow-up (Figure 27.6).[127] Interestingly, for this case, the scaffold was transplanted right after seeding without bioreactor conditioning, and SC engraftment was encouraged both by systemic granulocyte colony stimulating factor and human recombinant erythropoietin, associated with topical human recombinant erythropoietin and transforming growth factor β. Differently, endothelial and smooth muscle cells differentiated from the BM of the recipient were seeded on a decellularized donor iliac vein graft prior to transplantation in a 10-year-old girl with extrahepatic portal vein obstruction.[128] The graft was initially successful, but it was substituted after a year by a second tissue-engineered construct, which restored portal circulation. Decellularized tissue may, however, be not always the best. In 2001, a 4-year-old girl with a single right ventricle and pulmonary atresia, who underwent the Fontan procedure at the age of 3 years, was transplanted with a PCL–PLA copolymer (weight ratio, 1:1) reinforced with woven PGA seeded with autologous cells to bypass the total occlusion of the right intermediate pulmonary artery. Ten days after seeding, the graft was transplanted with no postoperative complications, and at 7 months the patient was doing well, with no evidence of graft occlusion or aneurysmal changes on chest radiography.[129]

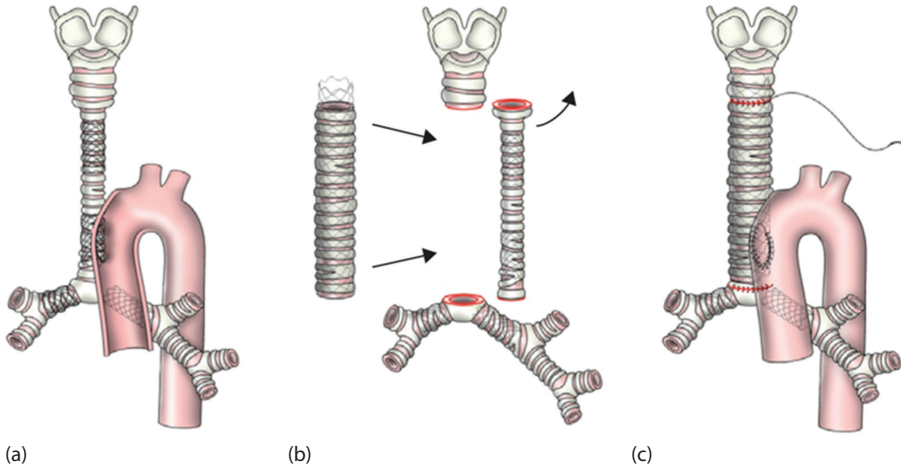

Figure 27.6 Schematic representation of the tissue-engineered trachea transplanted at Great Ormond Street Hospital in 2010. During surgery, the airway was found to be severely stenotic with multiple stents including one entering the ascending aorta **(a)**. The old homograft trachea was removed and replaced by the engineered graft. **(b)** The aortic defect was closed with a bovine pericardial patch and air leaks sealed **(c)**. (From Elliott, M. J. et al., *Lancet*, 380, 994–1000, 2012.)

More recently, a 36-year-old man, with recurrent primary cancer of the distal trachea and main bronchi, underwent excisional surgery followed by a reconstruction of his airway with a tailored bioartificial nanocomposite previously seeded with autologous BM mononuclear cells via a bioreactor for 36 hours.[130] More complex organs, such as the liver or the kidney, may require more time before being applied for therapy. Atala's group has described a perfusion decellularization technique for the liver and kidney generating decellularized organ scaffolds for organ bioengineering.[131] In an analogous fashion, Uygun et al.[132,133] have reported a successful approach of decellularizing rat livers and recellularizing them with rat primary hepatocytes, showing promising hepatic function and the ability to transplant heterotopically these bioengineered livers into animals for up to 8 hours. The decellularization approach was pioneered in the heart by Ott et al.[134] who showed that not only it was possible to generate whole organ scaffolds using a perfusion decellularization system but also that neonatal rat cardiomyocytes (delivered through transmural injection) and endothelial cells (injected through the aorta) could generate a contractile construct. Using a similar approach, lungs have also been regenerated through the seeding of pulmonary epithelium and vascular endothelium on rat lung ECM.[135] Among unmet clinical needs, intestinal engineering is particularly relevant, especially because of the relatively poor outcome of intestinal transplantation. However, although pioneering investigations in the field of intestinal bioengineering date back to the 1980s,[136] initial excitement has been blunted by the considerable limitations and roadblocks encountered in the course of experimental investigations. The main culprit of such stagnation is the complexity of intestinal anatomy and the various functions of the intestine. Vacanti's group showed that rodent organoid units seeded on a nonwoven PGA fiber and implanted in rats having undergone the resection of 85% of their native intestine were able to partially replace gut function.[137–139] Bioengineered intestinal constructs were also successfully transplanted in pigs (Figure 27.7),[140] but this technology is inefficient because several centimeters of bowel are needed to obtain a sufficient number of organoid units that are able to repopulate just a few centimeters of engineered intestine.[141] Intestinal SCs, which reside in the base of Lieberkuhn crypts and express Lgr5,[20,142] have been shown to be capable of building crypt–villus structures in vitro without any mesenchymal niche.[143] As these cells could be reliably expanded in culture, they could represent the ideal source of progenitor cells for intestinal bioengineering. Although representing only an initial step toward the ultimate goal of generating fully functional organs, decellularized matrices may help in understanding the functional structure of complex organs and may represent in the midterm the bridge for transplantation since some of these structures may be difficult to mimic artificially.[104] Those barriers could be overcome by producing three-dimensional vascularized cellular constructs of clinically relevant size, shape, and structural integrity. Very recently, we have witnessed the first report of an integrated tissue-organ printer that could fabricate stable, human-scale tissue constructs of any shape. Biodegradable polymers and hydrogels could be printed to the correct shape by representing clinical imaging data as a computer model of the anatomical defect and translating the model into a program that controls the motions of the printer nozzles, which dispense cells to discrete locations.[144] Using this integrated tissue-organ printer (ITOP) technology, the authors could demonstrate capabilities of the ITOP by fabricating mandible and calvarial bone, cartilage, and skeletal muscle. Future development of the ITOP may lead to the production of tissues for human applications and to the building of more complex tissues and solid organs.

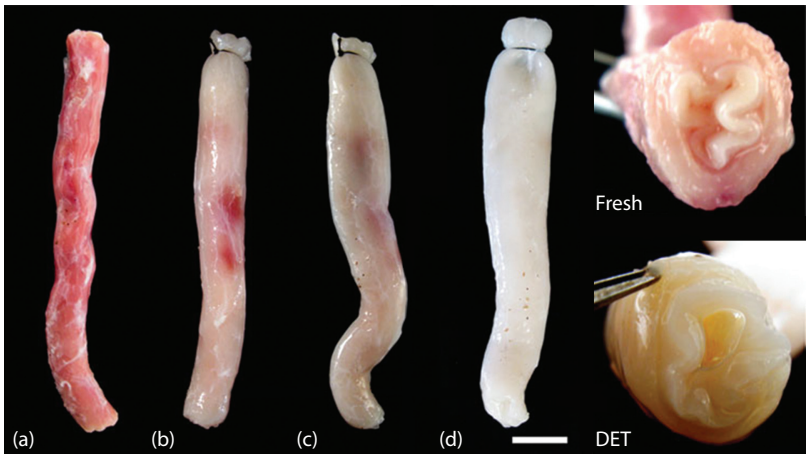

Figure 27.7 Decellularization of pig esophagus with detergent enzymatic treatment (DET) **(a–d)**. Macroscopic appearance of the esophagus during the decellularization process at cycle 0 **(a)**, 1 **(b)**, 2 **(c)**, and 3 **(d)**. The esophagus was perfused through the lumen with continuous fluid delivery, as described in the methods. The esophageal wall of the treated samples appeared gradually more translucent than the fresh tissue. Scale bar, 14 mm. (From Totonelli, G. et al., *Pediatric Surgery International* 29, 87–95, 2013.)

CONCLUSION

We are leading a very exciting time in medicine. Tissue and organ regeneration will revolutionize the treatment of diseases. It will be particularly interesting to observe the evolution of surgical approaches to malformations and organ transplantation, and the totally new possibility of correcting them using autologous tailor-made functional tissue.

Surgical aspects of HIV infection

ALASTAIR J. W. MILLAR, BRIAN ELEY, AND SHARON COX

INTRODUCTION

Pediatric HIV (human immunodeficiency virus) infection occurs predominantly in sub-Saharan Africa (SSA). Approximately 2.3 million HIV-infected children under 15 years reside in SSA, representing 88% of the 2.6 million children living with HIV in the world.[1,2] More than 90% of all HIV-infected children less than 15 years of age have acquired HIV through mother-to-child transmission during the antenatal period, at the time of delivery, or through breastfeeding. The risk of transmission can be substantially reduced by prevention of mother-to-child transmission (PMTCT) intervention programs that include the administration of antiretroviral therapy (ART) to all HIV-infected women during pregnancy and throughout breastfeeding, and antiretroviral prophylaxis to their newborn infants during the first 6–12 weeks of life[3,4] In 2015, the World Health Organization recommended that all HIV-infected pregnant and breastfeeding women should commence lifelong ART.[5,6] Substantial progress has been made in extending the coverage of PMTCT intervention programs. At the end of 2014, 73% of all pregnant and breastfeeding women with HIV infection throughout the world were receiving antiretrovirals to prevent mother-to-child transmission.[1] Despite the advances in preventing pediatric HIV infection, many HIV-infected and HIV-exposed but uninfected (HEU) children can be expected to require surgical procedures for the following reasons:

1. Emergency procedures to deal with a non-HIV-related life-threatening condition
2. Emergency procedures to deal with an HIV-related complication or disease
3. Nonemergency procedures where surgery is required to assist in the diagnosis of an HIV-related condition
4. Elective surgery for routine childhood procedures

Most studies on the outcome of HIV-infected patients undergoing surgery have been in adults.[7–10] These studies have reported conflicting results, but several suggested increased morbidity associated with HIV infection with little or no impact on mortality. In contrast, there is limited information on surgical presentations and outcomes in HIV-infected children.

For HIV-infected children presenting with life-threatening diseases for which surgery is urgently indicated, the emergent nature of these events does not allow preoperative correction of comorbidities such as malnutrition or the management of the immune deficiency with ART in children who are antiretroviral-naive. However, antimicrobial therapy may be started for those with coinfections and appropriate perioperative antibiotic prophylaxis prescribed.

Surgical procedures are frequently undertaken to assist in the diagnosis of an HIV-related pathology or complication. Most of these procedures allow time for preoperative treatment of premorbid conditions and coinfections, and initiation of cotrimoxazole prophylaxis and ART.[8,9,11]

Lastly there are increasing numbers of HIV-infected children who require routine, elective surgical procedures. The health status and life expectancy of these children should be taken into account when considering the timing and need for surgery. If surgery can be delayed, then comorbidities such as malnutrition and coinfections may be treated, cotrimoxazole prophylaxis commenced, and ART initiated. Treatment with ART for a period of 2–3 months or longer prior to the surgical procedure will suppress viral replication, will permit partial reversal of the HIV-related immunodeficiency, and may aid healing and lower the risk of postoperative infection, thus improving the overall surgical outcome.

Surgical problems associated with HIV infection may be classified into four major categories (Table 28.1):

1. Soft tissue or organ-specific infections requiring drainage or debridement
2. GI tract disease and complications
3. Infections in the perineal area
4. Malignancies

Table 28.1 Presentation, etiology/differential diagnosis, and indications for surgery in HIV-infected children

	Clinical presentation	Etiology/differential diagnosis	Surgical indications
Surgical infection	Abscess Necrotizing fasciitis Bloodstream infection	*Staphylococcus aureus* *Streptococcus* species *Candida* species Herpes simplex virus (HSV) Cytomegalovirus (CMV) Tuberculosis (TB) Molluscum contagiosum Gram-negative bacteria, e.g., *Pseudomonas* species	Drain pus Debride necrotic tissue Obtain culture to direct antibiotic therapy
Gastrointestinal disease and complications			
Esophageal diseases	Esophagitis Esophageal stricture	*Candida species* CMV HSV Idiopathic ulcers (HIV related) Malignancy, e.g., Kaposi sarcoma Non-HIV-related pathogens Gastroesophageal reflux	Contrast swallow to identify strictures Endoscopy with biopsy for histology and culture
Intra-abdominal problems	Gastrointestinal bleeding Gastrointestinal perforation Gastrointestinal obstruction	CMV TB *Mycobacterium avium-intracellulare* *Candida* species Malignancy, e.g., non-Hodgkin lymphoma	Endoscopy to diagnose GI bleeding Surgery for perforation and obstruction
Perineal disease	Anocutaneous fistula Condyloma Rectovaginal fistula Rectourethral fistula	CMV Human papillomavirus	Colostomy for sepsis with rectovaginal, rectourethral fistulae Cryotherapy or laser for condylomata
Malignancy	Depends on site and extent of disease	Non-Hodgkin lymphoma Karposi sarcoma Leiomyosarcoma	Biopsy of mass Surgical excision

INFECTIONS

Approximately 90% of HIV-infected children will develop mucocutaneous disease, which may be infectious or noninfectious.[11] Children with symptomatic HIV infection have an increased incidence of soft tissue infections (Figure 28.1). The cutaneous manifestations of HIV are indicators of underlying immune status. Bacterial skin infections are often recurrent, in atypical sites or due to atypical organisms (Figure 28.2).[12] The most common organisms causing skin infections are *Staphylococcus aureus* and *Streptococcus* species. These usually present as cellulitis, ecthyma, erysipelas, furunculosis (occasionally of disseminated nature), persistent and recurrent folliculitis, and impetigo. Pyomyositis is also increasingly reported, possibly associated with an increased risk of *Staphylococcus aureus* colonization. Gram-negative organisms may also cause severe, deep-seated skin infection in HIV-infected children. In particular, *Pseudomonas* species may produce cutaneous manifestations, including ecthyma gangrenosum and a papular rash, often in the perineal area.[13] Lethal mucormycosis infection can produce similar features (Figure 28.3a,b,c).[14]

Figure 28.1 Extensive suppurative cervical lymphadenitis with multiple anterior chest wall and upper limb soft tissue abscesses.

Figure 28.2 Noma (cancrum oris) polymicrobial necrotizing soft tissue infection of the face.

The principles of management of bacterial skin infection are as for HIV-unexposed children, including appropriate antibiotics and surgical drainage or debridement when needed. A high index of suspicion for rapidly spreading infection or necrotizing fasciitis must be maintained,[15] as the immune-compromised patient may not be able to mount an effective systemic response which is required to contain the infection.

Infection with molluscum contagiosum (Figure 28.4), a common viral infection due the DNA poxvirus, is frequent and is identical in appearance to that in HIV-unexposed patients but tends to be more extensive and recurrent, usually occurring on the face and neck.[16]

Immunization with live-attenuated bacillus Calmette–Guérin (BCG) vaccine soon after birth is widely practiced in low- and middle-income countries. This vaccine is typically administered intradermally on the right upper arm at the insertion of the deltoid muscle. Complications after immunization are common.[17] In healthy immunocompetent infants, a local reaction at the site of inoculation and nonprogressive ipsilateral axillary lymphadenopathy may occur. In HIV-infected children, site ulceration or abscess formation, suppurative ipsilateral axillary lymphadenopathy with or without fistulation (Figure 28.5a and b), and disseminated BCG infection may develop, especially after ART is commenced due to immune reconstitution inflammatory syndrome.[18] South African studies have shown that 6% of HIV-infected children develop BCG complications a median of 34 days after commencing ART, and 1% will develop disseminated BCG infection.[19,20] Vaccine site and regional lymphadenopathy complications follow a prolonged course but usually resolve spontaneously without specific intervention. Abscess drainage or surgical excision may be required. Disseminated BCG infection is treated with combination antimycobacterial therapy.[19,21]

GI TRACT DISEASE

Esophagitis is a common problem in HIV-infected children that can cause prolonged discomfort and malnutrition, compromise adherence to ART, and lead to increased morbidity

Figure 28.4 Extensive molluscum contagiosum on the face of an HIV-positive child.

and mortality.[22] Esophageal symptoms rank second only to diarrhea in frequency of GI complaints in HIV-infected children.[22] Esophageal disease may be a predictor of poor long-term prognosis, as it reflects severe underlying HIV immunodeficiency. Opportunistic infections are the leading cause of esophageal complaints. Treatment for most etiologies of esophagitis generally has a high degree of success, with a resultant improvement in quality of life especially with ART.[23]

The differential diagnosis for esophageal disease includes the following:

1. *Esophagitis or ulceration.* The causes are usually infective in origin, *Candida* species being the most frequent infection, followed by cytomegalovirus (CMV), herpes simplex virus, and idiopathic infective ulceration. Due to overlap of symptoms, endoscopy and biopsy are essential in identifying the pathology.[23] The growing number of effective antiviral and antifungal agents has mandated a more goal directed approach to therapy.
2. *Esophageal strictures.* The end result of untreated or extensive ulceration is likely to be stricture formation, occurring in approximately 10% of patients.[23] Strictures can be difficult to treat as they respond poorly to dilation and may require esophageal replacement surgery.[24]

Intra-abdominal pathology

The diagnosis and management of children with intra-abdominal surgical pathology can be challenging. Localizing signs and symptoms are frequently misleading due to underlying immunosuppression, debilitation, and antibiotic use. GI bleeding, distension, obstruction, perforation with abdominal pain, and tenderness are the most common clinical presentations associated with intra-abdominal diseases in HIV-infected children.[25]

GI bleeding represents an important source of morbidity and can result from opportunistic infections (CMV or *Candida* infection), HIV-associated malignancies (Kaposi sarcoma, leiomyosarcoma, or lymphoma) or may be unrelated to HIV infection.[26] Lower GI bleeding may be caused by CMV colitis, tuberculosis (TB), malignancy, or idiopathic colonic ulceration. Aggressive investigation with endoscopy to find the source of bleeding is required due to the wide differential diagnosis.[27]

Abdominal distension may occur secondary to chronic diarrhea, ileus, or obstruction. There are many causes for obstruction including inflammatory and infective causes, with TB predominating. Less commonly, neoplastic obstruction occurs secondary to lymphoma or Kaposi sarcoma. The obstruction may present due to invasive bowel infiltration by the tumor or from more localized disease and intussusception.[28] In neonates, the use of ART may mimic functional bowel obstruction.

(a) (b)

Figure 28.5 BCGosis. **(a)** Ulceration at the site of the BCG with surgically incised nodal abscess and **(b)** ulcerating nodal inflammation requiring surgical curettage.

Figure 28.6 Multiple antemesenteric small bowel perforations due to CMV in a child with HIV.

GI perforations may be secondary to CMV (Figure 28.6), TB, or lymphoma. Infants with chronic diarrhea may develop peritonitis due to intestinal perforation.[29] HIV-infected and HEU neonates with necrotizing enterocolitis may have a higher mortality and develop more extensive disease than unexposed infants.[30] Likewise, infants outside the neonatal period may develop necrotizing enterocolitis–type pathology after acute gastroenteritis with shock, which may result in extensive small and large bowel necrosis.

Abdominal pain as a presenting symptom may be due to medical or surgical causes. Infective and neoplastic conditions may present with abdominal pain. Several unique problems arise, however. Nucleoside reverse transcriptase inhibitors, used in ART regimens, may cause abdominal pain due to pancreatitis or lactic acidosis. Pain in the HIV-infected child must be fully investigated for medical and other drug-induced or surgical causes.

PERINEAL DISEASE

HIV-infected children have an increased rate of perirectal abscess and anocutaneous fistula. There are several reports of rectovaginal fistula and rectourethral fistulae or multiple fistulae with an increased rate of sepsis.[29,31,32] Management includes debridement and antibiotics, and on occasion, stool diversion with proximal divided colostomy. Definitive repair has been reported to have poor results but may be successful if preceded by initiation of ART.

Anal condylomata are rare in children, but an increased incidence occurs in HIV-infected children, who may present with extensive and/or recurrent lesions. Anal condylomata may or may not be associated with sexual abuse in HIV-infected children. Most cases of anal condylomata can be managed with cryotherapy, electrocoagulation, or ideally, CO_2 laser ablation under general anesthesia, taking care not to include the whole anal circumference to avoid anal stricture. A staged approach may be indicated if the lesions are very extensive.[33]

MALIGNANCY

HIV-infected children are at higher risk for malignancy than HIV-unexposed children, with tumors representing 2% of AIDS-defining events.[34] Kaposi sarcoma (Figure 28.7), non-Hodgkin lymphoma (NHL), and cervical cancer are AIDS-defining events.[35] Although rates of leiomyosarcoma and leiomyoma are higher in HIV-infected patients, they are regarded as non-AIDS-defining tumors. Kaposi sarcoma is the most common malignancy in HIV-infected individuals in Africa because human herpes virus-8 infection is highly prevalent in Africa and precedes the development of Kaposi sarcoma. NHL is the second most common HIV-associated malignancy in Africa but the most frequent HIV-associated malignancy in other parts of the world. Epstein–Barr virus infection often precedes the development of NHL. A recent South African study confirmed that Karposi sarcoma and NHL are the most frequently occurring malignancies in HIV-infected children. Furthermore, the risk of developing cancer was lower on ART, but increased with age and the degree of immunodeficiency.[36] These malignancies are treated with a combination of ART, chemotherapy, and radiotherapy. Surgery is usually limited to tissue biopsy or to the treatment of complications.

Incidental solid tumors must be treated as for HIV-unexposed children, although coexisting disease, specifically TB, should be considered during the investigation of solid tumors for metastatic spread.[34] This group of coinfected patients has been reported to have a high mortality independent of the primary tumor type. An HIV-infected child with malignancy should be started on ART as soon as possible. The widespread introduction of ART has lengthened life expectancy, which may result in an increased lifetime incidence of solid organ malignancy in HIV-infected children.[37,38]

Figure 28.7 Mesenteric nodal involvement with Kaposi sarcoma in a child presenting with intussusception due to small bowel Kaposi sarcoma lesions.

MEDICAL ASPECTS OF PEDIATRIC HIV INFECTION AND THEIR EFFECT ON SURGERY

HIV-infected children have a greater risk of community- and hospital-acquired bacterial infections. These infections may be more severe, follow a protracted course, or result in a worse outcome compared to their HIV-unexposed counterparts. Bacterial infection can involve any organ system or present as bloodstream infection without a clinical focus. Infections may be polymicrobial or caused by drug-resistant pathogens, which has implications for the selection of perioperative prophylactic antibiotics.[39,40]

Reduced pulmonary reserve and an increase in pulmonary complications are of concern after major surgery.[39] HIV-infected children have a high incidence of pulmonary complications, which may be infective or noninfective. Respiratory involvement in HIV-infected children can involve either the upper or lower airway, with implications for airway management during anesthesia.[41] Adenotonsillar enlargement can cause upper airway obstruction and difficult endotracheal intubation. There is an increased incidence of chronic lung disease in HIV-infected children; this may impact on the anesthetic and perioperative management.[42] Lastly, the increased risk of infection may lead to nosocomial pneumonia complicating the postoperative course.

TB coinfection is common in HIV-infected children in low- and middle-income countries. Drug–drug interactions between rifampicin-containing TB drug regimens and other therapies including antiretroviral drugs create pharmaceutical challenges that may impact on the selection of drugs including anesthetic agents and analgesics for children requiring surgery.[5]

Hematological manifestations of HIV include anemia, neutropenia, lymphopenia and thrombocytopenia.[3,43] Anemia has been repeatedly identified as a strong, independent risk factor for HIV disease progression and death. Severe thrombocytopenia and anemia correlate with advanced disease and poor prognosis. Thrombocytopenia can complicate surgical procedures by increasing bleeding and the need for blood products, leading to increased complications in the perioperative period.

GI dysfunction including diarrhea, nausea and vomiting, dysphagia, or odynophagia causes significant morbidity among HIV-infected children. Abdominal surgery may result in a postoperative ileus. This together with preexisting intestinal dysfunction can make postoperative fluid management and feeding challenging. Furthermore, odynophagia and dysphagia may be secondary to lesions, which are friable and thus easily traumatized during airway instrumentation or insertion of a nasoenteric tube, causing bleeding or perforation.

Malnutrition is one of the most frequent and severe complications of pediatric HIV infection, increasing morbidity and mortality. Analysis of approximately 18,000 HIV-infected children in five southern African countries showed that at the start of ART, 50% were underweight, 66% stunted, and 16% wasted.[44] Malnutrition has been reported to be an independent risk factor for an adverse surgical outcome.

HIV-infected children are at risk for the development of metabolic complications, some of which may be secondary to HIV infection or ART. The surgical and anesthetic implications of such complications must be considered in the overall management of HIV-infected children, including during the perioperative period.[41,42]

Postoperative pain control in HIV-infected children can be challenging. For adequate pain control, a combination of medications may be needed, increasing the potential for drug–drug interactions in children who are often receiving ART or other drugs.[45]

OUTCOMES OF HIV-INFECTED CHILDREN UNDERGOING SURGERY

Few prospective data exist on the outcomes in HIV-infected children undergoing surgery.[46,47] The first reports of surgical outcomes in children with HIV infection were brief, focusing on the procedures performed and risk of transmission of HIV to health care workers. Subsequently, a few case series reported HIV-specific surgical conditions in children without describing the outcome or complications of surgical intervention, although a neonatal subgroup was reported to have a high postoperative mortality of 30%. Most of these children reported on did not receive ART.

Several case reports or case series of procedures have been published, raising concerns of poor wound healing and complications.[46,48,49] A recent series of 48 HIV-infected children undergoing minimally invasive surgery (MIS) for diagnostic and therapeutic procedures concluded that MIS could be safely performed on HIV-infected children but that certain routine procedures such as fundoplication were more difficult and prone to complication.[50] The largest series of HIV-infected and HIV-exposed children undergoing surgery was published in 2009, but this report focused on the disease presentations and only alluded to a higher morbidity; furthermore, no control group existed in that study.[51] There is only one prospective cohort study undertaken comparing the outcomes of HIV-infected and HIV-unexposed children, which noted that HIV infection was the most important risk factor for development of a complication postsurgery, associated with an almost 12-fold higher risk. There was also a significantly higher mortality and longer length of stay.[2]

FACTORS INFLUENCING POSTSURGICAL COMPLICATIONS

Several factors may impact on the rate of postoperative complications in HIV-infected children.[2,52] ART has reduced mortality and morbidity, improved the quality of life, and

slowed disease progression of HIV-infected children.[53,54] It suppresses viral replication, leading to a reduced plasma HIV viral load, reversal of CD4 cell attrition, improved overall immune function, and lower risks for infection and HIV-associated malignancy. Two adult studies have investigated the use of ART as an independent predictor of surgical complications. In both studies, three-drug ART regimens were administered for at least 2–3 months prior to surgery. Neither study found that ART reduced postoperative complications. Similarly, in pediatric studies, short-term perioperative ART was not found to be associated with a statistically significant decreased risk of postoperative complications. Thus, delaying elective surgery for the institution of short-term ART may not seem sensible.[55] However, whether or not a longer period of preoperative ART resulting in a greater degree of immune recovery will improve surgical outcomes has not been subjected to rigorous scientific evaluation.

A study that assessed the outcome of anorectal surgery in HIV-infected adults showed that only 40% of patients had healed their wounds by 3 months postsurgery. Wound healing was significantly delayed when the absolute CD4 count was <50 cells/μL. However, clinical stage of HIV infection, age of the patient, and serum albumin concentration were not significant predictors of wound healing.[56] In another study that evaluated the outcome of HIV-infected adults requiring invasive or surgical procedures, preoperative total white blood count, postoperative absolute CD4 count, and postoperative plasma viral load were associated with mortality, postoperative CD4 count was an independent predictor of both postoperative infection and other complications, and a decrease in CD4 percentage was an independent predictor of postoperative complications other than infection.[57]

Only one pediatric study has assessed predictors of postoperative complications in HIV-infected children undergoing surgery. Although this study was limited by sample size and a high proportion of children with advanced HIV disease, it found that only age less than 1 year and major surgery were predictors of postoperative complications. Malnutrition, clinical stage of HIV infection, ART, and type of surgery were not associated with postoperative complications.[55]

HIV-EXPOSED BUT UNINFECTED CHILDREN

A consequence of the success of PMTCT intervention programs is that there are now countless numbers of HEU infants and children in the world, primarily located in low- and middle-income countries. Compared to HIV-unexposed children, HEU infants and young children are at an increased risk of morbidity and mortality, primarily from infectious causes.[30,58] A recent study showed that HEU children are twice as likely to require hospitalization for invasive pneumococcal disease and those less than 6 months of age are less likely to survive an episode of invasive pneumococcal disease than HIV-unexposed children.[59] Reasons for the increased risk of infection in HEU infants are multifactorial, including adverse social factors associated with being born into an HIV-affected household, often shortened duration of breastfeeding, and higher risk of malnutrition. In addition, a range of immunological changes have been reported in HEU infants predisposing them to a spectrum of infections.[60] Susceptibility to infections may increase the risk for developing complications in the postoperative period. Poor growth and malnutrition may also impact on outcomes postsurgery, increasing the risk for infections and delayed wound healing. In a prospective study, it was noted that HEU children had a higher risk of developing postoperative complications and mortality than HIV-unexposed children, but this risk was lower than in HIV-infected children.[30]

CONCLUSION

HIV-infected children may present with conditions unique to HIV infection and common surgical conditions. HIV exposure confers an increased risk of complications and mortality for all children following surgery, whether or not they are HIV-infected. However, the risk of complications is much higher in HIV-infected patients. These findings seem to be independent of whether patients undergo an elective or emergency procedure, but the risk of an adverse outcome is higher after a major surgical procedure. Early treatment with ART is associated with reduced mortality in HIV-infected infants and children. However, further studies are required to optimize the duration of ART prior to surgery.

Liver transplantation

ALASTAIR J. W. MILLAR AND CWN SPEARMAN

INTRODUCTION

History

One of the prime stimuli for the development of liver transplantation was the inevitable mortality from infant liver disease, and many of the advances in liver transplantation techniques were prompted by the need to tailor the procedure for the pediatric patient. The first ever human transplant was attempted in 1963 by Starzl[1] on a 3-year-old child with biliary atresia. The infant did not survive the operation, and it was not until 4 years later that he obtained "success" in achieving survival for 400 days in an 18-month-old girl with a malignant liver tumor. She died from disseminated metastases. Over the next decade, 1-year mortality remained high at around 50%, and it was not until cyclosporine was introduced in 1980 that survivals dramatically increased. In June 1983 at the National Institutes of Health Consensus Development Conference, liver transplantation was declared a valid treatment for end-stage liver disease. The introduction a decade later of tacrolimus, a more potent calcineurin inhibitor, pushed the boundaries of success even further. Technical advances included reduced-size liver transplantation,[2] split-liver, transplants,[3] and living related transplants.[4]

Advances in patient selection, organ preservation, surgical technique, anesthetic management, preoperative and postoperative care, and refinements in immunosuppression and management of the immunosuppressed patient over the last four decades have resulted in a much improved outcome with an ever-increasing list of indications being identified (Table 29.1).[5]

In infancy, the most frequent reasons for liver transplantation are infantile liver failure due to neonatal hemochromatosis and biliary atresia.

The current United Network for Organ Sharing pediatric Kaplan–Meier predicted overall patient and graft survival at 1 year is 86%–93% and 78%–87%; at 5 years, 77%–86% and 63%–75%; and at 10 years, 75% and 61%, respectively.

The survival figures vary according to recipient age at time of transplant: Overall 1-year patient and graft survival were 89% and 81%, respectively, in recipients aged <1 year; 86% and 78%, respectively, in recipients aged 1–5 years; 91% and 84%, respectively, in recipients aged 6–10 years; and 93% and 87%, respectively, in recipients aged 11–17 years. Overall 5-year patient and graft survival was 78% and 63%, respectively, in recipients aged <1 year; 77% and 67%, respectively, in recipients aged 1–5 years; 86% and 75%, respectively, in recipients aged 6–10 years; and 81% and 67%, respectively, in recipients aged 11–17 years.[5,6]

Excellent quality of life is the rule rather than the exception but does, to some extent, depend on pretransplant morbidity, particularly from the nutritional deprivation, which occurs with chronic liver function impairment and cholestasis, leading to neurodevelopmental delay. The longest survivor is in good health 46 years after transplantation. Current anxieties over organ donor scarcity militating against timely transplant, the long-term side effects of the immunosuppressive therapy, financial implications, and some ethical issues remain. The focus of attention has now shifted from an initial target of early posttransplant survival to quality of life in the long term. Shortage of donor organs has been tackled in an imaginative way with increasing use being made of size reduction of the donor liver even into a single segment, splitting the liver into two functioning units for two recipients, as well as the use of living related donors and non-heart-beating donors.

INDICATIONS

Liver disease has been generally underestimated as a cause of death in infants and children. This is probably because many liver conditions in children have led to rapid deterioration and death in the past. Pediatric liver transplantation is now established as routine treatment for children dying of end-stage chronic liver disease and acute/subacute liver failure in both developed and developing countries (Table 29.1). Almost all forms of liver disease in children

Table 29.1 Indications for which liver transplantation has been performed in children

I. Metabolic (inborn errors of metabolism)
(a) Alpha-1 antitrypsin
(b) Tyrosinemia
(c) Glycogen storage disease types III and IV
(d) Wilson disease
(e) Perinatal hemochromatosis
(f) Hypercholesterolemia
(g) Cystic fibrosis
(h) Hyperoxaluria (preemptive or with renal transplant)
(i) Hemophilia A + B
(j) Protein C deficiency
(k) Crigler–Najjar syndrome
(l) Urea cycle defect
II. Acute and chronic hepatitis
(a) Fulminant hepatic failure (viral, toxin, or drug induced)
(b) Chronic hepatitis (B, C, etc.; toxin, autoimmune, idiopathic)
III. Intrahepatic cholestasis
(a) Neonatal hepatitis
(b) Alagille syndrome
(c) Biliary hypoplasia
(d) Familial cholestasis
(e) Primary sclerosing cholangitis
IV. Obstructive biliary tract disease
(a) Biliary atresia
(b) Choledochal cyst with cirrhosis
V. Neoplasia
(a) Hepatoblastoma
(b) Hepatocellular carcinoma
(c) Sarcoma
(d) Hemangioendothelioma
VI. Miscellaneous
(a) Cryptogenic cirrhosis
(b) Congenital hepatic fibrosis
(c) Caroli disease
(d) Budd–Chiari syndrome
(e) Cirrhosis from prolonged parenteral nutrition

can be complicated by hepatocellular failure. These include acute and subacute liver failure from metabolic, toxic, or viral insults, and chronic parenchymal disease of varying causes, of which biliary atresia, biliary hypoplasia, autoimmune hepatitis, viral hepatitis, and some metabolic diseases are the most common.[5] The widespread introduction of vaccines for both hepatitis A and B has significantly reduced the incidence of acute liver failure. In some metabolic diseases, the manifestations are hepatocellular, and in others, there may be more widespread systemic effects such as with tyrosinemia, Wilson's disease, hyperglycoproteinemia, some glycogen storage diseases, and primary hyperoxaluria. New treatments for acute liver failure due to neonatal hemochromatosis using antenatal intravenous immunoglobulin (IVIG) for the mother and exchange transfusion and IVIG for the newly diagnosed neonate may reduce the need for liver transplantation in this group of patients.[7,8]

In infants with type 1 primary hyperoxaluria, an innovative strategy may be that of early preemptive liver transplantation, perhaps preventing the need for later renal transplantation.[9]

Hemangioendothelioma in infancy is an occasional indication, if medical treatment with steroids, propranolol, and surgical treatment with resection, hepatic artery ligation, or embolization fails, but outcome is guarded.[10]

Children with cystic fibrosis with good respiratory reserve may require an isolated liver transplant for early-onset progressive liver disease.

Intestinal failure–associated liver disease (IFALD) develops in 40%–60% of infants who require long-term total parenteral nutrition. Isolated liver transplantation may be a lifesaving option for infants with short bowel syndrome and IFALD, when adaptation can be expected. Revised criteria for isolated liver transplantation include the following: progressive IFALD; 50 cm functional bowel in absence of the ileocecal valve (ICV) or 30 cm with ICV; and 50% daily energy intake tolerated enterally for 4 weeks with satisfactory growth. Children with a dysmotile bowel should be assessed for a combined liver–bowel transplant unless the dysmotility is resolved and associated with minimal line infections. Nontransplant surgery may be required to facilitate full adaptation, but a >50% long-term survival can be expected.[11]

ASSESSMENT

In general, liver transplantation should be considered as a therapeutic option in all cases of chronic liver disease before the complications of end-stage liver disease arise and in acute liver failure with defined parameters indicating a poor prognosis.

There are indeed few contraindications to liver transplantation (Table 29.2). These include uncontrolled systemic bacterial, viral, or fungal infections; malignancy outside the liver; cyanotic pulmonary arteriovenous shunting with pulmonary hypertension; active chronic hepatitis B; HIV/AIDS not controlled with antiviral treatment; as well as other major cardio-respiratory and/or neurological disease, which would be incompatible with quality long-term survival. To a certain extent, these are all relative contraindications. Psychosocial factors may be a reason for refusal. Parental substance abuse, severe psychiatric problems, and poor preoperative adherence with therapy are factors that need to be carefully examined. In developing countries, the socioeconomic factors such as poor sanitation and lack of access to adequate medical follow-up are often contraindications to transplantation.

Adherence is more difficult to predict in families of children with acute liver failure, as time from presentation to

Table 29.2 Contraindications to liver transplantation

- Poor socioeconomic circumstances—no access to electricity, running water—social worker evaluation required
- History of poor compliance with medications and medical follow-up—social work evaluation required
- No access to ongoing medical care and monitoring of graft function and immunosuppressive drug levels
- Severe cardiopulmonary disease
- Concomitant end-stage organ failure that cannot be corrected by a combined transplant
- Severe multisystem mitochondrial disease
- Irreversible serious neurological damage
- Uncontrolled sepsis
- HIV/AIDS—requires special evaluation and control of infection with HAART
- HBV infection unless prophylaxis with HBIG and antivirals available
- Extrahepatic malignancy (exception: Hepatoblastoma with isolated pulmonary metastases responsive to chemotherapy)
- HCC outside Milan criteria
- Cholangiocarcinoma

Relative contraindications

- Portal vein thrombosis (extensive splanchnic venous thrombosis)
- Previous extensive upper abdominal surgery
- Hemophagocytic lymphohistiocytosis
- Parents with life-threatening illnesses, unless there is an appropriate long-term substitute caregiver for pediatric transplant patients

Table 29.3 Investigation of the liver transplant candidate

A. Full symptom history and physical examination	
B. Hematology:	Complete blood count, clotting profile
	Blood group and tissue typing
	Serum biochemistry and liver function tests
C. Radiology:	Chest and abdominal x-ray
	X-ray wrists and long bones
D. Imaging:	Ultrasound with Doppler for size and flow in the portal vein and unusual anatomy. CT with contrast or magnetic resonance angiogram if a vascular anomaly is suspected
E. Renal function:	Urine analysis, biochemistry, and creatinine clearance
F. Cardiopulmonary:	Full evaluation, particularly if hepato-pulmonary syndrome is clinically evident
G. Serology:	Hepatitis A, B, C, CMV, EBV, HSV, HIV, measles, and varicella
H. Infection screen:	Cultures of urine, sputum, blood, stool, ascites fluid, and swabs from nose and throat. Dental check
I. Nutritional evaluation:	Micronutrients: iron, zinc, selenium, manganese, and vitamin levels A and E
J. Developmental assessment	
H. Psycho-social assessment	

decision to transplant is much shorter. Good adherence is one of the factors thought to contribute to the slightly better outcome after living-donor transplantation as the bond and responsibilities between donor and recipient are that much greater.

As the outcome of the operation is so much better in recent years, indications for early transplant in patients with chronic liver disease would be evidence of impaired synthetic function, including prolonged prothrombin time, reduced serum cholesterol levels, and low serum albumin. Clinical indicators include presence of ascites, bleeding from esophageal varices not controlled by sclerotherapy/banding, and poor response to nutritional resuscitation. Those with acute liver failure who develop encephalopathy, hypoglycemia, a prothrombin time of greater than 50 seconds, and a factor V level of less than 20% should be considered for transplant, as almost all of these children die without transplantation.

All patients require initial confirmation of the diagnosis, intensive medical investigation, nutritional resuscitation, and active treatment of the complications of the liver disease, portal hypertension, and nutritional deprivation (Tables 29.3 and 29.4). Immunization status must be reviewed and supplemented as required with hepatitis A and B, hemophilus influenza, pneumococcal, varicella, meningococcal, and human papilloma virus immunizations. It is important that live attenuated vaccines are given pretransplant, as these are contraindicated posttransplantation. Blood group–identical or –compatible donors are much preferred as the long-term survival with blood group–incompatible donors has been significantly less, but there have been recent reports of excellent outcomes with blood group incompatibility particularly in infants under 1 year of age.[12] If urgent transplantation is required, an incompatible ABO blood group donor organ can be considered. There are also specific strategies to reduce the potential adverse immune consequences of a blood group–incompatible organ including the use of a CD20 monoclonal antibody, IVIG, and plasma exchange.[13]

Table 29.4 Evaluation of the patient pre-transplant

- Confirm the indication for transplant
- Determine severity of the liver disease and nutritional status
- Consider alternative treatments to transplant
- Identify and treat active infections
- Identify cardiac malformations that need correction pre-transplant
- Ensure that immunizations are up to date, especially live vaccines (measles and varicella) that are contraindicated post-transplantation
- Dental care
- Evaluate psycho-socioeconomic factors and logistics

Educate and counsel parents and medical caregivers about

- Pre-transplant waiting period and potential death on the waiting list
- Transplant procedure regarding the risk of surgery, especially technical complications such as vascular thrombosis and biliary complications
- Post-transplant complications of rejection, risks of immunosuppression, malignancy, and recurrent disease

Children with chronic liver disease are prioritized for liver transplantation according to the PELD (Pediatric End-Stage Liver Disease) (under 12 years) or MELD (Model for End-Stage Liver Disease) (12 years and older) score. Children presenting with acute liver failure are listed as UNOS Status 1a (this includes children <18 years old presenting with fulminant liver failure, primary graft nonfunction, hepatic artery thrombosis, acute decompensated Wilson's disease, and nonmetastatic hepatoblastoma). Children with chronic liver disease (PELD > 25) who are in the ICU and who have at least one of the following: on ventilator; gastrointestinal bleeding requiring at least 30 mL/kg packed red cell transfusion in previous 24 h; renal failure requiring dialysis; Glasgow coma scale < 10 are classified as UNOS Status 1b.

Young age (<6 months), creatinine clearance (<90 mL/1.73 m^2), pretransplant hospitalization, pretransplant ventilation, retransplantation, and transplant for reasons other than cholestatic disease have been associated with a reduced survival.[14] Predictors of graft loss include the type of graft (split graft and reduced-size graft), donor age <5 months, prolonged warm ischemia time, and fulminant liver failure as indication for liver transplantation.[15]

SURGICAL TECHNIQUE

Donor organ suitability and function are difficult to predict. Increasingly, marginal donors are being used with a surprisingly low incidence of primary poor function or nonfunction. Age limits are being extended. However, stable donors aged under 45 years with a short intensive care unit stay (less than 3 days), little requirement for inotropic support and normal, or near-normal liver function are preferred, with an expected <5% incidence of impaired function after transplant. Liver biopsy is useful if steatosis is suspected. Greater than 50% fatty infiltration would preclude the use of the liver in most centers. Viral screening of the donors is essential and includes the following: hepatitis B (HBsAg, anti-HBV IgG core, and nucleic acid test [NAT]); hepatitis C (hepatitis C antibody and NAT); cytomegalovirus [CMV] IgG Ab; Epstein–Barr virus [EBV] IgG Ab; and HIV (HIV combined Ag/Ab test and NAT) screening. Use of hepatitis C virus (HCV)-positive donor livers should only be considered for HCV-positive recipients, as HCV transmission is universal.

Surgical techniques used for donor retrieval and recipient liver removal and engraftment have evolved over the last 40 years.[5,16,17] The majority of donor livers are removed as part of a multiorgan procurement procedure, which would include various combinations of kidneys, liver, heart or heart and lungs, small bowel, and pancreas. University of Wisconsin solution and histidine–tryptophan–ketoglutarate solution (HTK) are both widely used as the preservation solutions of choice.[18]

The principle two techniques is a careful dissection and excision technique or the so-called rapid technique described by Starzl.[17,19]

Donation after cardiac death has been an established practice for many years for renal transplantation, but recently, in an effort to expand the donor pool, this has been extended to other organs. The concept of cardiac death may be more acceptable to some and could increase the number of potential donors. Although there are considerable logistic problems to overcome, some success has been achieved with acceptable graft function even in segmental liver transplantation using a "super-rapid" technique and keeping both cold and warm ischemic times to a minimum.[20]

The graft should be of an appropriate size to provide adequate function but not too large to compromise the abdominal compartment domain. A minimum graft size should be >0.8% of body mass (normal ~2%), i.e., 40% of estimated standard liver volume. Grafts of smaller size have a poorer outcome from graft failure due to small-for-size (SFS) syndrome.

The *recipient operation* is commenced so that the estimated hepatic graft cold ischemic time is less than 12 hours. Much longer preservation times have been recorded, but this leads to an increased incidence of cholestasis and graft dysfunction.

Careful dissection of the graft is required when split-liver transplantation is being used, that is, when the liver is divided into two functional units for two recipients, and decisions must be made as to which porta hepatis structures will go with which graft. It is advisable to perform a portable cholangiogram to confirm bile duct anatomy, as there are many variations in biliary anatomy. Depending on local preference, many centers opt to export the right-sided graft with the full complement of structures of bile duct, portal vein, and hepatic artery, keeping the left lateral segment as the graft for a pediatric recipient in much the same way as a living-donor transplant. Where a reduced-size liver

is used, the caudate lobe is always excised. The division of liver tissue may be performed using the standard forceps clamp or bipolar diathermy technique with titanium clip and/or suture and ligation of vascular and biliary structures. The ultrasonic dissector (Cavitron Ultrasonic Surgical Aspirator), Ligasure or Harmonic Scalpel may also be used. The cut edge of the liver is then sprayed with two layers of tissue glue. If the recipient inferior vena cava is to be preserved, this is simply done by carefully excising the diseased liver clear of the cava and, when the liver has been removed, individually suturing closed all small areas of leakage from divided direct caudate lobe hepatic veins. The IVC is prepared for the donor liver by dividing the bridges between the separate hepatic veins. This creates a wide orifice for the hepatic vein-to-cava anastomosis. The inferior vena cava should also be incised distally for approximately 1–2 cm to make a triangular orifice for the piggy-back graft.[21]

Engraftment should begin with the upper caval anastomosis taking into account the need to rotate the liver anticlockwise about 60 degrees with reduced-size liver grafts. Split grafts and living-donor segmental grafts may need to lie in an orthotopic anatomical position, and a number of techniques of stabilizing the graft have been used so as to avoid torsion at the hepatic vein-to-caval anastomosis and to facilitate vascular anastomoses without using interposition grafts. Prior to completion of the anastomosis, the liver is flushed of preservation solution via the portal vein with recipient blood, normal saline, or a colloid solution. It is important for the portal vein to be of adequate size and length, and it should lie without tension. If the recipient vein is too narrow and sclerotic, interposition of a donor iliac vein is indicated.[17] Likewise with the arterial anastomosis, if the recipient vessel is too small or the donor artery too short, an interposition graft is placed onto the supraceliac or infrarenal aorta. The bile duct is trimmed back and spatulated in pediatric donors such that there is good bleeding from the cut edge and a wide anastomosis is obtained. With reduced- and variant-size grafts, a Roux-en-Y choledochojejunostomy is always performed using fine absorbable sutures.[5]

Occasionally in pediatric cases, a duct-to-duct anastomosis may be performed with a whole liver graft in a recipient with a normal extrahepatic biliary system or for infants with short bowel syndrome undergoing isolated liver transplant. Stents or T tubes are optional but less used as there is some evidence of an increased incidence of biliary complications associated with their use.

SPLIT-LIVER TRANSPLANTATION AND LIVING DONATION

In split-liver transplantation, a whole cadaver donor organ is divided into two functional units. Segments 2 and 3 are used for an infant and the right liver for an adult recipient. The graft can be further reduced in size by removing segment 2, or alternatively, segment 2 is used as the graft, and segment 3 is resected and discarded. The disadvantage of using a segment 3 graft is the greater anterior posterior dimension, which may be difficult to accommodate in an infant abdomen (Figure 29.1).[22] Living related donation of the left lateral segment, first successfully performed by Strong, has become widely accepted as a method of acquiring a liver graft in the face of severe donor shortages, particularly in countries with cultural or religious reticence to accept brain death in a ventilated heart-beating donor. There are clear advantages in the planned nature of the procedure preferably before end-stage liver disease in the recipient, the excellent quality of the graft, and short ischemic time. The use of a living donor also increases the availability of donor organs in general for other patients on the waiting list. The only advantage to the donor is a psychological one, and there is a current morbidity of around 10% (wound sepsis, hernia, bile leak, and adhesive bowel obstruction). There is also a reported mortality of around 0.2%, although in one center in Japan, more than 1000 of these operations were done without donor mortality.[23] There are ethical concerns, which appear justified, as with more widespread transplant activity, increasing mortality and morbidity have been recorded in adult-to-adult donation, but adult-to-child donation has a very low morbidity and mortality. The donor should first undergo a thorough screening both clinical and psychological without coercion and be given an option to withdraw from the procedure at any time before the transplant.[24,25] This process may have to be accelerated where donation is for fulminant hepatic failure. Cholangiography is essential as there is considerable variety in the intrahepatic biliary anatomy. Angiography is desirable but not essential.

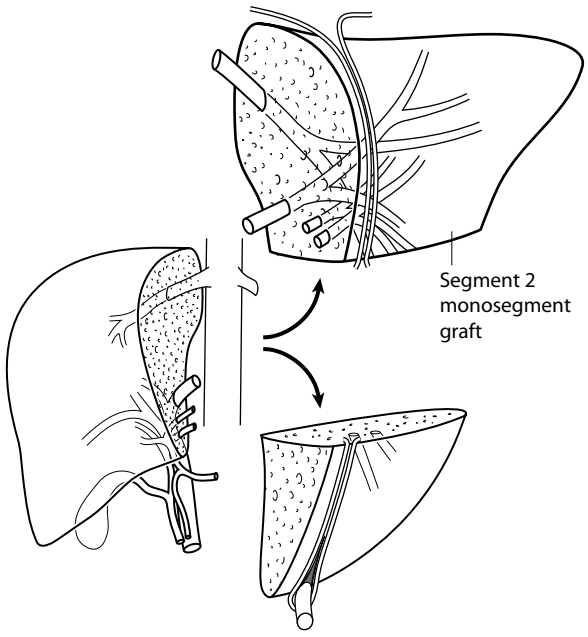

Figure 29.1 Left lateral segment transplant from a living donor or split liver, further reduced in size to a monosegment graft by resection of segment 3. (From Oliveira P, Biliary complications after paediatric liver transplantation, *Pediatr Transplant* 2010 May;14(3): 437–8.)

Magnetic resonance (MR) imaging has made interventional radiographic techniques obsolete.

MEDICAL MANAGEMENT

Immunosuppression

There is no standard-of-care immunosuppression regimen, and chosen regimens are often determined by cost, particularly in resource-constrained countries, where the cost of induction agents, tacrolimus, and mycophenolate mofetil is often prohibitive.

Immunosuppressive regimens should, in addition to preventing acute and chronic rejection, promote good quality of life and be free of significant long-term side effects. Calcineurin inhibitors remain the cornerstone of immunosuppression, with tacrolimus being the preferred agent.[26] Tacrolimus is associated with lower incidences of both acute and chronic rejection,[27,28] hypertension, and hyperlipidemia, and does not cause hirsutism and gingival hyperplasia.[27,29]

Induction immunosuppressive regimens are usually a combination of calcineurin inhibitors (cyclosporin or tacrolimus) and steroids with variable use of an antimetabolite (azathioprine or mycophenolate mofetil). Maintenance monotherapy with tacrolimus or cyclosporine is the target, and attempts should be made to wean steroids by 3–6 months, but there is a risk of developing de novo autoimmune hepatitis following the cessation of steroids.[30,31] If steroids are required, aim for low-dose alternate-day steroids to encourage growth, as short stature is a significant side effect in young children.[32]

According to the Organ Procurement and Transplant Network (OPTN)/Scientific Registry of Transplant Recipients (SRTR) 2014 annual report, the most commonly used initial immunosuppression agents in North America were tacrolimus (94.8%), steroids (82.1%), and mycophenolate mofetil (39.7%). Only 31.8% received induction therapy (18.3% IL-2 [interleukin 2] receptor antagonists and 13.5% a T-cell-depleting agent). Among recipients, 1.4% were reported to have received a mammalian target of rapamycin (mTOR) inhibitor at the time of transplantation, but this increased to 8.2% at 1 year posttransplantation. Despite the long-term side effects, 55% of recipients were still on maintenance steroid therapy at 1 year.[6]

Both cyclosporin and tacrolimus cause a 30% reduction in renal function, and up to 5% of pediatric transplants develop severe chronic renal failure.[33] Renal-sparing regimens with IL-2 receptor blockers as induction therapy often in combination with mycophenolate mofetil enable delayed introduction of calcineurin inhibitors in the setting of pretransplant renal dysfunction, use of low-dose tacrolimus, as well as enabling the more rapid weaning or even avoidance of steroids.[34–38]

Sirolimus, an mTOR inhibitor has also been used as a renal-sparing and an immunological rescue agent[39] but is potentially hepatotoxic, can cause proteinuria, and increases serum triglyceride levels. Other side effects include a delay in wound healing and hepatic artery thrombosis, and it is thus not recommended in the early postoperative period. Children with posttransplant lymphoproliferative disease or hepatoblastoma may benefit from immune suppression with sirolimus.[40] Everolimus has not been registered for use in pediatric liver transplantation.

Postoperative care

Patients are monitored intensively postoperatively and usually require ventilation for a period of 24–48 hours. Liver ultrasound with color flow Doppler is performed frequently to confirm vascular patency and the absence of biliary dilatation.

Acute postoperative hypertension is almost universal in pediatric transplantation and persists in 25% of recipients. It is usually initially managed with oral amlodipine in titrated doses. Subsequently, ACE (angiotensin-converting enzyme) inhibitors and beta-blockers may be given in appropriate dosage. Aspirin 3 mg/kg given on alternate days is used as prophylaxis against arterial thrombosis, and a proton pump inhibitor is given for gastric mucosal protection.

Early enteral feeding and vitamin supplementation is advised, and if delayed beyond 48 hours of surgery, parenteral nutrition should be commenced. Phosphate and magnesium deficiency is common and requires replacement therapy in nearly all patients.

Liver biopsies are performed if indicated by increasing serum liver enzyme activity or by bilirubin levels, using the Menghini technique (Hepafix needle [Braun], diameter 1.4 mm), unless biliary dilatation is observed on ultrasonography. Biopsies are routinely assayed for viral and bacterial activity.

Diagnosis of rejection can be made on the basis of clinical, biochemical, and histologic changes and usually presents in the first few weeks after transplant with fever, malaise, a tender graft, and loose stools. The grade of rejection is assessed according to established histological criteria (lymphocyte- predominant portal infiltrates, cholangiolar damage, and endotheliitis) according to the Banff schema.[41]

Management of acute cellular rejection in the early postoperative period depends on the induction immunosuppressive regimen but is less problematic in children who are on Tacrolimus-based regimens and have received induction therapy with IL-2 receptor blockers. It is important to ensure adequate trough tacrolimus levels (10–15 ng/mL), substituting mycophenolate mofetil for azathioprine. If there is ongoing rejection, pulsing with intravenous methylprednisone can be used, but this is seldom necessary with present-day immunosuppressive regimens. The patient should be given four doses of methyl prednisolone at 10 mg/kg, the first three doses on successive days and the fourth dose on the fifth day after commencing treatment. IL-2 receptor blockers and T-cell-depleting agents are very rarely used for steroid resistant rejection. Once rejection is under control and liver function tests have returned to normal, steroids are weaned, and the tacrolimus dosage can be reduced, aiming for a trough level of 5–10 ng/mL at

6–12 months posttransplant, 3–8 ng/mL at 13–24 months posttransplant, and 2–4 ng/mL after 2 years.

Anti-infection agents

Immunosuppression naturally leads to increased susceptibility to bacterial, fungal, protozoal, and viral infections. Antibiotics are given as prophylaxis and according to culture and sensitivity of blood, sputum, and body fluid. In infants, there is a low threshold for antifungal therapy with either amphotericin or fluconazole. Caspofungin can be considered in children with impaired renal function. Ganciclovir is given as prophylaxis against CMV and EBV infections for 100 days, initially intravenously, but once stable, valganciclovir can be given orally.

Trimethoprim/sulfamethoxazole is routinely given for 6 months for pneumocystis jirovecci prophylaxis and can be restarted at times of increased immunosuppression.

Antituberculosis prophylaxis is given only if the reason for transplant is a reaction to antituberculosis drugs with fulminant hepatic failure, where evidence of tuberculosis is found before surgery and if a close family contact has tuberculosis.

First-line antituberculous therapy (isoniazid, rifampicin, ethambutol, and pyrazinamide) can be used in children with normal graft function, but regular monitoring of liver function tests is required as these drugs are potentially hepatotoxic. It is important to monitor tacrolimus/cyclosporin levels as rifampicin induces the cytochrome P450 system, resulting in increased drug metabolism. Tacrolimus or cyclosporin dosage should empirically be increased by 30% at the start of antituberculous therapy.

Surgical complications

Surgical complications may be reduced to an absolute minimum with meticulous technique (Table 29.5).[5,20] These may present early and late. Biliary complications continue to be a significant problem with an overall incidence of 10%–20%, particularly in living related left lateral segment grafts.[42] A proactive management approach is taken with close monitoring of vascular patency using Doppler ultrasound scanning and computed tomography (CT) or MR angiogram if there is any doubt. Radiological intervention techniques have been used successfully for later complications of biliary strictures and portal vein stenosis. SFS syndrome is a recognizable clinical scenario where the liver graft size is unable to meet the functional demands of the recipient in the absence of other causes for graft dysfunction. Grafts of less than 35% graft volume relative to standard liver volume or 0.8% of graft:recipient weight ratio (GRWR) are considered small for size. The liver failure presents toward the end of the first posttransplant week with coagulopathy, ascites, cholestasis, and encephalopathy and is often associated with pulmonary and renal dysfunction. The underlying pathophysiology is complex but is universally associated with a high portal vein blood flow (usually >250 mL/minute per 100 g graft weight) and is aggravated by any hepatic vein outflow obstruction. The histological appearance shows marked congestion, dilatation of sinusoids and portal veins, scattered areas of necrosis, and severe cell denudation with neutrophilic inflammatory cell infiltrate. Strategies for avoiding SFS syndrome include avoiding small grafts, ensuring short ischemic times, and modulating portal vein flow. Splenic artery ligation at the time of transplant or embolization in the early postoperative period has been efficacious in reducing portal hypertension and improving outcomes.[43–45] Various types of partial portal vein decompression maneuvers have been tried both experimentally and in small clinical series. Medical management to reduce splanchnic flow includes somatostatin infusion and propranolol. Intraportal

Table 29.5 Summary of common postoperative problems

1. **Biliary tract**
   (a) Stenosis or stricture
   (b) Anastomotic leak—often associated with hepatic artery thrombosis
   (c) Cholangitis
2. **Rejection**
   (a) Acute
   (b) Chronic (vanishing bile duct syndrome)
3. **Infection**—bacterial, viral (CMV, EBV, herpes zoster, hepatitis B), fungal (candida, aspergillus), parasitic (pneumocystis)
   (a) Abdominal (perihepatic or intrahepatic abscess)
   (b) Biliary tree
   (c) Pulmonary
   (d) Reactivated virus
   (e) Gastrointestinal tract
   (f) Catheter associated (intravenous, urinary tract)
4. **Vascular (thrombosis, stenosis)**
   (a) Hepatic artery
   (b) Portal vein
   (c) Inferior vena cava (suprahepatic and infrahepatic)
   (d) Hepatic vein (left lateral segment grafts), Budd–Chiari recurrence
5. **Renal dysfunction**
   (a) Calcineurin inhibitor–induced or other drug-induced injury
   (b) Tubular necrosis due to hypoperfusion
   (c) Preexisting disease (hepatorenal syndrome)
   (d) Hypertension
6. **Miscellaneous**
   (a) Encephalopathy (cyclosporin, tacrolimus, hypertensive, metabolic)
   (b) Bowel perforation (steroid, diathermy, hypoxia)
   (c) Diaphragm paresis/paralysis
   (d) Gastrointestinal hemorrhage (peptic ulceration, variceal)
   (e) Obesity (steroids)
   (f) Other drug side effects

infusion of prostaglandin E1 and thromboxane A2 have also been used.[46]

Medical follow-up and late complications

Most patients can be discharged from the intensive care unit within the first week after transplantation.[5,20] The majority of infections can be prevented. However, should the patient require excessive immunosuppression for persistent rejection, almost inevitably, he/she will develop some opportunistic infections.

In this situation, not only must specific therapy be directed at the pathogen, but also, immunosuppression must be reduced. CMV and EBV are best monitored with quantitative polymerase chain reaction (PCR) measurement of the virus.

Posttransplantation lymphoproliferative disorder (PTLD) presents from the first few weeks after transplant to several years later with a mean time of onset around 9 months. Risk of PTLD relates to the intensity of immunosuppression (5%–7% in liver transplant recipients) and pretransplant EBV status. Regular EBV PCR monitoring and appropriate reduction in immunosuppression reduces the risk.[47] A typical presentation is initially with acute membranous tonsillitis and associated cervical lymphadenopathy, which is resistant to antibiotic therapy. However, the disease may be widespread, and gastrointestinal and central nervous system involvement is common. Management strategies include reduction of immunosuppression, which may require complete withdrawal along with chemotherapy, anti-CD20 monoclonal antibodies, and adoptive immunotherapy, particularly with the monoclonal PTLD.[48] Mortality varies from 20% to 70% or more. Prophylactic ganciclovir initially intravenously followed by oral valganciclovir given for 3 months may be effective in preventing EBV activation, which is the promoter of PTLD in most cases.

The rates of de novo hepatitis B associated with the use of hepatitis B IgG core antibody–positive donors in the absence of HBV prophylaxis are 58% in HBV nonimmune, 18% in previously vaccinated, 14% in isolated anti-HBV IgG core positive, and 4% in naturally immune (HBsAb and anti-HBV IgG core positive) individuals.[49] Lifelong Lamivudine is recommended as the most cost-effective option to prevent de novo hepatitis B from the use of hepatitis B IgG core antibody–positive donors.[50]

If children are transplanted for hepatitis B, then prophylaxis with hepatitis B hyperimmunoglobulin (HBIG) and an antiviral with high genetic barrier to resistance such as tenofovir or entecavir is recommended. Entecavir is recommended for children aged 2–11 years and tenofovir in children ≥12 years and weighing at least 35 kg. Lamivudine has to be used in children under the age of 2 years. There is no consensus regarding the duration, dosage, and mode of administration of intravenous injection [IVI] or intramuscular injection [IMI] HBIG, but antivirals should be given lifelong to prevent recurrence of chronic hepatitis, which is inevitable without prophylaxis.[51]

Children are frequently hypertensive and require antihypertensive therapy for a period of time posttransplant. A degree of renal impairment is almost inevitable in those patients suffering from chronic liver disease with cholestasis. With the additional burden of the use of nephrotoxic immunosuppressive drugs such as cyclosporin and tacrolimus, many have significant impairment of renal function in the long term. The importance of renal-sparing strategies in immunosuppression is becoming increasingly evident as 4%–5% long-term survivors present with drug-induced renal failure requiring renal replacement therapy.

Chronic rejection is an irreversible phenomenon, which is chiefly intrahepatic and ductular rather than a vascular phenomenon, in contrast to other organ transplants. This is usually manifested by disruption of bile duct radicals with development of the vanishing bile duct syndrome. The incidence seems less frequent with tacrolimus-based immunosuppressive regimens as opposed to cyclosporine, where an incidence of up to 10% has been recorded. Late chronic rejection may also be associated with a vasculopathy affecting larger arteries.

RETRANSPLANTATION

Retransplantation rates have improved, with OPTN/SRTR reporting rates as low as 8.8% for the period 2012–2014.[6] Early indications include primary graft nonfunction; early hepatic arterial thrombosis, and refractory acute cellular rejection; and later-established chronic ductopenic rejection. Early retransplantation is technically a much less traumatic procedure than the original transplant, although the patient may be in a poorer condition. Outcome largely depends on the indication for retransplantation and is quite good for technical causes but less satisfactory for rejection and infection. An increasingly poorer outcome can be expected after the third and fourth retransplants, and the efficacy and ethics of these interventions are in question.

LONG-TERM SURVIVAL AND QUALITY OF LIFE

One-year patient survival of >95% is being achieved in the best centers, with predicted 10-year patient survivals of around 70%–75%.[5,6] Patients grafted for acute liver failure have done less well, with a higher early death rate usually associated with cerebral complications and multiorgan failure. Overall, excellent quality of life can be achieved, and most children are fully rehabilitated.[52,53]

It is, however, increasingly evident that prolonged cholestatic jaundice and malnutrition in infancy may have late effects, and despite good physical rehabilitation, evidence of significant cognitive deficits, which present during early schooling as learning difficulties and attention deficit disorders, is common.[54]

Catch-up growth post liver transplant improves if steroids are reduced, used on alternate days, or withdrawn.[32] But with steroid withdrawal comes the risk of development of chronic rejection or de novo hepatitis.[30,31,55] As with any

immunosuppressed patient, the incidence of neoplasia in a lifetime is greatly increased (12% skin and other malignancies).[56] Renal function impairment aggravated by hypertension and calcineurin inhibitor and antibiotic toxicity is frequent, with up to 25% developing chronic renal failure at 10 years posttransplant.[57]

Fibrosis on histology is an increasingly recognized phenomenon, which seems to be more related to factors at the time of the transplant (cold ischemic time, young age, donor:recipient weight ratio, use of partial grafts) rather than immunological or infective factors.[58]

At a workshop on long-term outcomes, the following factors were identified as requiring further research: risk factors associated with long-term immunosuppression complications; development of tolerance-inducing regimens; definition of biomarkers that reflect the level of clinical immunosuppression; development of instruments for the measurement of health wellness; identification of risk factors that impede growth and intellectual development before and after liver transplantation; and identification of barriers and facilitators that impact nonadherence and transition of care for adolescents.[59]

ADOLESCENCE

Nonadherence in adolescent transplant recipients (~20%) is a particular concern[60] In addition to coping with the usual issues of autonomy, peer pressure with regard to alcohol, recreational drugs, and sex, the transplant teenager has to cope with the cosmetic side effects of immunosuppression, regular medical monitoring, and strict adherence to drug regimens.[61] These issues often occur at the time of transfer to an adult unit. It is important to actively involve teenagers in the decision making, and discuss issues of sexuality, risks of pregnancy, and appropriate contraception. A planned transfer to an adult program is essential as the risk of nonadherence and graft loss is great during this period. Adolescents who have undergone transfer to the adult transplant services at a median age of 18.6 years have had good long-term outcomes.[62]

Transplantation in infancy appears to result in a reduced incidence of nonadherence in adolescence compared with later transplantation. Use of mobile phone text messaging has been shown in one study to reduce nonadherence amongst teenagers.[63]

CONCLUSION

Careful planning, extensive preparation of personnel, and a broad base of skills along with good teamwork between health professionals are required for the development of a successful pediatric transplant program. Surgical technique, anesthetic skills, and medical care of the highest order are essential. Size of the recipient is only important insofar as making the graft fit the recipient abdomen but long-term outcomes are excellent.

A patient with a liver transplant is a patient for life and requires complete commitment from the transplant medical and surgical team, which cannot be abrogated after discharge from hospital. However, it is essential to set up an effective shared care program with the referring medical caregiver, as many recipients will reside far from the transplant center.

The need for pediatric liver transplants has been assessed at approximately 1 to 2 children per million per year. Thus, transplant activity should be concentrated in specific centers with pediatric surgical and medical expertise. The shortage of donor organs will continue, and future efforts must be focused on maximum use of cadaver donors and increasing living related donation. No child with end-stage liver disease should be denied the opportunity of receiving appropriate treatment.

These challenges must be met to offer any infant or child requiring liver replacement a chance at a life. The ultimate aim is to restore the child to normal health such that he/she can grow up into a productive healthy adult who can make his/her contribution to society and develop all of his/her human potential.

Choanal atresia

MIRA SADADCHARAM AND JOHN D. RUSSELL

INTRODUCTION

Choanal atresia is a well-recognized congenital defect characterized by obstruction in the posterior nasal apertures, usually by bone or soft tissue, secondary to failed recanalization of the nasal fossae during fetal development (Figure 30.1). This defect was first reported by Johann George Roederer in 1755 and was later characterized as an anatomic deformity of palatine bone by Adolf Otto in 1854.[1] The condition may be either unilateral or bilateral. Bilateral choanal atresia presents acutely in the neonatal period as an airway emergency, in view of the fact that neonates are obligate nasal breathers. The classic clinical scenario is one of increasing respiratory distress that improves when the child starts to cry, since he/she takes in air through the mouth, thus bypassing the obstructed choanal airway. A unilateral defect may go undetected for months or even years prior to diagnosis. Treatment may be divided into emergent and elective definitive categories and involves surgical repair of the defect. Following the first successful transnasal corrective surgery by Carl Emmert in 1854, surgical techniques have evolved from transmaxillary, transseptal, transpalatine, and sublabial intranasal approaches to modern endoscopic techniques. Despite the acceptance of the endoscopic approach as the current gold standard, controversies still exist on how to best manage patients with this condition, particularly regarding the use of adjuvant topical medications following surgical repair and the use and duration of postoperative stenting.[2]

EPIDEMIOLOGY

Choanal atresia occurs in approximately 1 in 5000–8000 live births. The ratio of unilateral to bilateral choanal atresia is 2:1, with the right side being more commonly affected in unilateral cases. Although choanal atresia does not appear to have a particular racial demographic, studies report that the female-to-male ratio for infants with choanal atresia is 2.2:1.[3] In addition, while no correlation appears to exist between maternal age and parity, there does appear to be a slightly increased incidence in twin births. Approximately 50% of all patients have other associated congenital abnormalities, which rises to approximately 75% in patients with bilateral disease.[4] The atretic plate may be either mixed, bony, or membranous in nature. A 90% rate of bony stenosis and 10% rate of membranous stenosis were classically reported, but modern imaging suggests a mixed bony/membranous obstruction in 70% and a pure bony obstruction in 30%.[5] Associated syndromes include CHARGE (coloboma, heart defect, atresia choanae, growth and mental retardation, genital hypoplasia, ear anomalies); Crouzon; DiGeorge; amniotic band syndrome; fetal alcohol syndrome; and Treacher Collins.

EMBRYOLOGY AND THEORIES OF CAUSATION

In humans, development of the face and cranial structures occurs in the first 12 weeks of gestation. Specifically, the choanae develop between the 4th and 11th weeks.[6] At 4 weeks' gestation, nasal development begins with the formation of nasal pits. At approximately 5 weeks' gestation, these nasal pits deepen and invaginate into the surrounding mesenchyme to form the nasal sacs, separated from the primitive oral cavity by oronasal membranes. At about 8 weeks' gestation, these membranes rupture to create a nasal cavity and primitive choanae located at the junction between the nasal cavities and the nasopharynx. By the end of the 10th week of gestation, the nasal septum and the developing palate fuse and the primitive choanae undergo alteration and are pushed posterior. At this stage, the choanae are termed secondary choanae. In a normal fetus, secondary choanae are patent, allowing for a functionally patent airway between the anterior part of the nose and the inner nasopharynx.[6]

In choanal atresia, the abnormality is complex, representing more than just an obstruction membrane across the posterior choanae. The lateral nasal wall and medial pterygoid plates form part of the obstruction and need to be addressed during the surgical repair.[7] The boundaries of the atretic plate are composed of the undersurface of the

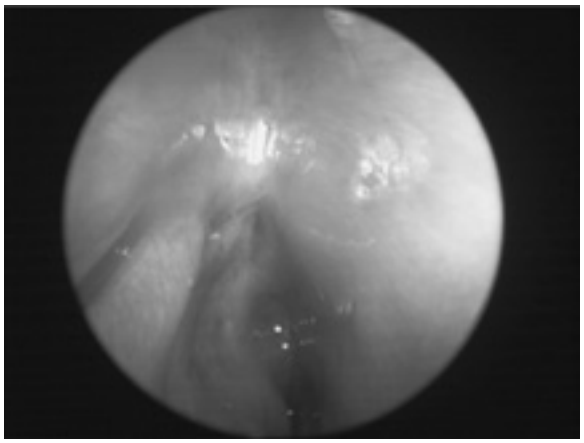

Figure 30.1 Endoscopic view of a right-sided choanal atresia as viewed from the nose.

sphenoid body superiorly, the medial pterygoid laterally, the vomer medially, and the horizontal portion of the palatine bone inferiorly.

Over the past two decades, four theories have gained prominence when investigating the etiology of choanal atresia. These are as follows: (1) persistence of the buccopharyngeal membrane from the foregut; (2) abnormal persistence or location of mesoderm-forming adhesions in the nasochoanal region; (3) abnormal persistence of the nasobuccal membrane of Hochstetter; and (4) misdirection of neural crest cell migration and subsequent mesodermal flow.

Currently, the theory of misdirection of neural crest migration and subsequent mesodermal flow is thought to offer the strongest evidence. During embryogenesis, the ectoderm at the neural plate margin produces neural crest cells. These cells subsequently migrate to form the skeletal and connective tissue framework of the face and portions of the cranium. Neural crest cell deficiencies have been associated with defects in the frontonasal parts of the face. Furthermore, disordered migration patterns have been found to be associated with caudal maxillary process and visceral arch derivatives as seen in choanal atresia.[8] Craniofacial anomalies with mesenchymal damage and cell disruption were found in offspring of mothers who took high doses of vitamin A, and these changes were associated with embryonic pathways involving the migration of neural crest cells in early fetal life.

Environmental risk factors for choanal atresia have not been well studied. Maternal behaviors, including lifestyle and nutritional intake during pregnancy, play an important role in optimal fetal development and outcomes. Women of reproductive age may be exposed to cigarette smoke, alcohol, caffeine, suboptimal nutrition, and medications, each of which has been associated with birth defects.

Barbero et al.[9] suggested that prenatal use of antithyroid medications, e.g., methimazole and carbimazole, were linked to choanal atresia. In addition, Lee et al.[10] evaluated the association between continuous and categorical infant T_4 levels and nonsyndromic choanal atresia and suggested a role of low thyroid hormone levels in the development of choanal atresia. They further suggested that low newborn T_4 levels could potentially be used as a proxy measure of risk.

The CHARGE association is associated with choanal atresia in approximately 30% of cases.[11] All patients diagnosed with choanal atresia should have a systematic examination for other features of the CHARGE association.

CLINICAL PRESENTATION

The clinical presentation of choanal atresia is dependent on whether the deformity is unilateral or bilateral and the presence of other coexisting comorbidities. Bilateral choanal atresia presents as an airway emergency at birth, since neonates are obligate nasal breathers for the first 6 weeks of life. Physical examination often demonstrates a bony and/or membranous obstruction in the nasal cavity, stridor, marked retraction of the chest, and paradoxical cyanosis (blueness of skin relieved by crying). Acute airway stabilization including insertion of an oral (Guedel) airway, use of a McGovern nipple (a nipple from a feeding bottle with the end opened to allow respiration), or even intubation is required in the first instance. Once the airway has been secured, it is important to consider differential diagnoses including pyriform aperture stenosis and severe neonatal rhinitis. Subsequent investigations should be targeted at both confirming the diagnosis and assessing for the presence or absence of associated comorbidity.

Unilateral atresia may be picked up in the newborn period during routine nasal catheter screening. However, if the catheter rolls up in the nasal cavity, choanal atresia may not be diagnosed until later, when the child presents with unilateral nasal obstruction (no misting of mirror) and an associated thick unilateral foul-smelling nasal discharge.

RADIOLOGIC INVESTIGATIONS

Traditional plain radiography in the supine position with the nasal cavity filled with radiopaque contrast has been replaced by computed tomography (CT). CT of the paranasal sinuses and skull base is recognized as the investigation of choice. Ideally, the nasal cavity should be suctioned prior to the scan as thick mucus can be hard to differentiate from a membranous atretic plate. Thin-section (1–2 mm) axial images provide the best view of the obstruction, but coronal reconstructions should also be provided to identify intraoperative landmarks. CT helps to accurately delineate the location of obstruction within the nasal passages, the position (anterior, posterior), laterality (unilateral, bilateral), and histological characteristics (bony, membranous, or mixed) of each affected choana. Prior to the availability of CT, the histological distribution of choanal atresia cases was estimated as 90% bony and 10% membranous.[12] More recent findings using CT and tissue specimens suggest that about 30% of choanal atresia is pure bone and 70% is mixed (membranous and bone), with no pure membranous occurrence.[13,14]

MANAGEMENT

Treatment of choanal atresia aims at establishing the patency of the airway, preventing further damage to the surrounding structures, and a short intervention with limited hospitalization. Infants with bilateral choanal atresia will require airway stabilization with at least an oropharyngeal airway as outlined previously. Such devices need to be carefully taped in place and an orogastric tube passed to facilitate feeding until definitive surgical repair can be attempted. Surgical repair should be performed early (even in the first week of life) in patients with bilateral atresia. The only contraindication to early correction is the presence of associated comorbidities, e.g., cardiac anomalies in those patients with the CHARGE association. Children with unilateral atresia can generally wait until 1 year of age, when the risk of general anesthetic has diminished. Occasionally, patients with unilateral atresia have significant airway difficulties and will require earlier intervention.

Since the first reported repair of choanal atresia by Carl Emmert in 1854, a number of surgical techniques have been described. Transnasal puncture of the atretic plate using urethral dilators was initially performed blindly. However, this technique has now largely been superseded by endoscopic resection using powered instruments.[1]

Endoscopic resection

This approach is preferred by the authors as it allows excellent visualization of the operative field. A tonsil (Boyle–Davis) mouth gag is inserted and a Vicryl suture placed through the uvula and clipped to facilitate retraction of the soft palate. A 120° 4 mm endoscope is passed through the mouth into the nasopharynx and a view of the posterior surface of the obstructed choanae obtained (Figure 30.2). The nasal cavity is decongested with 1:10,000 adrenaline patties, and the atretic plate injected with 1% lignocaine with 1:200,000 adrenaline. If present, the membranous component of the atretic plate is then perforated with a small suction catheter or urethral dilator. The 120° telescope is passed through the mouth to view the atretic plate at the time of perforation (Figure 30.3). The senior author then uses the Acclarent sinuplasty balloon for further atraumatic dilatation. The drill is then inserted through the nose until it reaches the nasopharynx. The senior author uses a specialized drill (Medtronic), which has a protective sheath over the shaft, preventing trauma to the nasal cavity. The drilling is performed medially over the vomer and laterally over the medal pterygoid plates. The posterior aspect of the vomer is then removed using a back-biting forceps into the nasopharynx and removing the posterior half of the vomer. This creates a common cavity posteriorly, which minimizes the chance of restenosis. Beclomethasone drops are applied in the immediate postoperative period to minimize edema. The child is electively taken back to the theatre 6 weeks postoperatively, at which point any granulations present are removed with a microdebrider and any restenosis dilated.

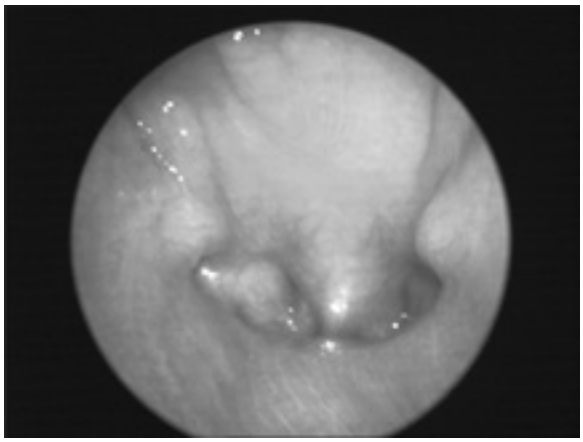

Figure 30.2 Endoscopic view of choanal atresia from the nasopharynx as viewed through a 120° telescope.

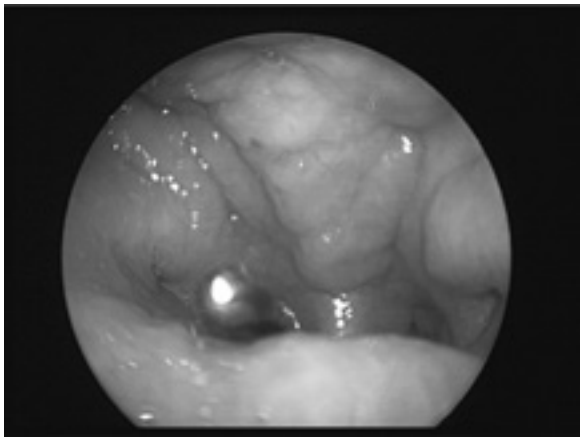

Figure 30.3 Endoscopic view of urethral dilator being passed through an atretic plate as viewed from the nasopharynx using a 120° telescope.

Multiple procedures for further microdebridement and dilatations are often required, with one large series reporting an average of 4.9 procedures.[12] A number of variations of the endoscopic technique are reported.[1] The most common variation from our technique is a complete transnasal approach using the 0° 4 mm (or 2.7 mm in neonates) telescope. We find the sole use of the transnasal approach to be associated with difficulty using two instruments in the same nasal cavity, particularly within the context of limited space available in the neonate. Similarly, mucosal-sparing flaps are advocated by some surgeons in an attempt to improve re-epithelialization.[13,14] However, the authors' experience is that these flaps are difficult to perform in the limited space of a neonatal nose, and they are generally not viable at the end of the procedure. CT-based image guidance systems are now widely used in pediatric endoscopic nasal surgery.[15] While not mandatory, we advocate their use in this procedure if available.

Transpalatal resection

The transpalatal approach was the first approach to the choanal abnormality that provided good exposure of the operative field. Together with simple blind dilatation, it remained the mainstay of surgical repair until the advent of endoscopic technology and techniques. In this procedure, a U-shaped incision is made over the hard palate 5 mm from the dental arch. A posteriorly based subperiosteal flap is elevated to gain access to the nasopharynx. The inferior vomer is encountered and removed prior to drilling of the lateral atretic plate. This technique remains useful in patients with a small nasopharynx and low skull base, such as infants with Treacher Collins syndrome, or where an endoscopic approach has failed. The transpalatal approach is associated with a higher complication rate compared to endoscopic techniques. Potential complications include postoperative pain, palatal fistula, and reduced midface face growth leading to a high arched palate and associated dental malocclusion, which occurs in approximately 50% of patients.[5]

Adjuncts to surgery

STENTS

The use of postoperative nasal stents continues to be controversial. Significant debate exists in the literature as to whether placing stents in the operative site after the procedure provides improved outcomes. Portex and manipulated endotracheal tubes are often used. When stents are used, the optimum duration of use is unclear with the literature reporting a range of 24 hours to 12 weeks.[1]

As a proponent of stenting, Friedman et al. reviewed 46 cases of choanal atresia and reported a favorable prognosis (defined as fewer operations needed) with children who had stents in for greater than 12 weeks.[16] Following this in 2004, Gujrathi et al.[17] performed a study on 52 patients who had stents in place for a median of 12 weeks. They found that only 2 of 52 (3.8%) patients required a revision operation. Despite this, stents are not without potential side effects, with necrosis of the external nose, septum, and palate reported.[17] Furthermore, stents have a tendency to become blocked with secretions, requiring lavage and suctioning on a routine basis by both the parents and the nursing staff. Several opponents to stenting make claims against its efficacy, often citing how there is a significant foreign body tissue reaction with the stent in place, leading to more granulation tissue and scarring down of the tissues. Schoem[18] demonstrated this in a study of 13 patients who did not have stents placed, with 4 of the subjects requiring no further operations and 9 of them requiring only one additional operation. More recently in 2013, Llorente et al.[19] demonstrated similar outcomes without stents, having 100% patency in their test subjects at 27 months' follow-up.

MITOMYCIN C

In addition to stents, the antineoplastic agent mitomycin C has been used as a treatment adjunct to try to decrease stenosis. Mitomycin C is an aminoglycoside that is produced by the bacteria streptomyces. It works by inhibiting fibroblast growth and proliferation, which may help minimize the granulation tissue. This drug is already commonly used in other areas of head and neck surgery. It is typically applied as a topical agent on a cotton pledget for a few minutes in the nose to achieve the desired effect. A study by Holland and McGuirt[20] demonstrated promising outcomes with the use of the drug. The study involved 8 test subjects and 15 controls. The primary outcome measure was the number of dilations required after initial surgery. They found that patients treated with adjunctive mitomycin C therapy required significantly fewer dilations than the control group.

CONCLUSIONS

When faced with a neonate or older child with signs of nasal/upper airway obstruction or respiratory distress, it is important to consider the possibility of a unilateral or bilateral choanal atresia. If choanal atresia is identified, it is necessary for the physician to investigate for the coexistence of associated conditions. If bilateral atresia is identified, this should be managed as an airway emergency and appropriate measures taken to secure the airway prior to considering surgical intervention.

When undergoing surgical treatment, one must consider the most effective approach and possible treatment adjuncts to give the patient the best outcome possible. A considerable array of surgical techniques (including adjuvant therapies) exist for the management of choanal atresia in the newborn.

The primary outcome measure is restenosis as evidenced by a need for reoperation. Reported revision rates for endoscopic resection vary from 0% to 36%.[1,11] Restenosis appears more likely to be required in patients who undergo surgery in the neonatal period for bilateral disease and suffer from gastroesophageal reflux. Favorable outcomes may be predicted by the absence of associated facial anomalies, higher weight at the time of surgery (>2.3 kg), and larger stent size.[21,22] One long-term study has demonstrated moderate hyposmia in adults who underwent bilateral choanal atresia repair as a child.[23]

To date, no randomized control trials exist to determine optimum treatment protocols, even for the more controversial questions such as the role of postoperative stenting. Unfortunately, due to overall rarity of the condition, this absence of evidence is likely to remain unchanged, and management guidelines will continue to be based on personal reports and case series.

Pierre Robin sequence

UDO ROLLE, ARANKA IFERT, AND ROBERT SADER

INTRODUCTION

The condition is originally named after the French dental surgeon Pierre Robin (1867–1950). He described micrognathia (firstly named "mandibular hypotrophy"), glossoptosis, and respiratory distress in his first paper.[1] In a later publication, Pierre Robin added cleft palate to the list of clinical signs.[2] There had been previous reports of the triad micrognathia, cleft palate, and glossoptosis resulting in dyspnea and cyanosis.[3–5] Pierre Robin added the term "glossoptosis" to better characterize the tendency for the tongue to fall back and cause pharyngeal obstruction.

The traditional name for the condition used to be "Pierre Robin syndrome," but after 1975, a series of nosologic changes took place, including Robin anomalad,[6] Robin malformation complex,[7] and then Robin sequence (PRS).[8]

The term "sequence" is used to reflect the hypothesis that the three cardinal symptoms develop sequentially, though it is still not proven what the correct sequence is. The traditional hypothesis states that a mandibular anomaly leads to an anomalous palate (cleft palate) and subsequent airway obstruction.[9] Even if this concept seems to be supported by animal experiments,[10] actual functional therapy results also support the opposite hypothesis that a malpositioned tongue leads to altered mandibular growing patterns.[11–13]

ETIOLOGY, PATHOPHYSIOLOGY

The most accepted etiological hypothesis is the hypoplasia or abnormal development of the mandible around 7–11 weeks gestational age displaces the tongue high within the nasopharynx.[14] Others comprise oropharyngeal and muscular deficiency or mandible compression in utero.[15] In mandible hypoplasia, the tongue, unable to descend because of either the lack of mandibular growth or severe retropositioning of the mandible, obstructs the palatal shelves from fusing. The cause of the growth insult to the mandible is uncertain and, presumably, is of heterogeneous etiology. Reported possible causes included (1) positional or mechanical deformation, as in oligohydramnios, which can be caused by a number of factors; (2) intrinsic mandibular hypoplasia, as in numerous congenital malformation syndromes; (3) neurological or neuromuscular abnormalities, such as myotonic dystrophy or arthrogryposis; and (4) connective tissue disorders, such as Larsen syndrome.

In all these cases, sequential events would lead to the changes seen in PRS. A logical assumption is that a variety of factors may lead to persistent mandibular hypoplasia with the resulting postnatal manifestations.[16] Since mandibular abnormalities might have numerous causes, PRS cannot be regarded as a specific disease entity. A differentiation should be made between isolated PRS and patients in which PRS is part of a recognized syndrome, part of a complex of multiple anomalies, or part of an unrecognized syndrome.

GENETICS, INCIDENCE

There is a high incidence of twins with PRS. Furthermore, family members of PRS patients have a higher incidence of cleft lip and palate.[17] Cleft palate is associated with deletions of 2q and 4p, and duplications of 3p, 3q, 7q, 78q, 10p, 14q, 16p, and 22q. Micrognathia is associated with deletions of 4p, 4q, 6q, and 11q, and duplications of 10q and 18q.

The proportion of the number of cases with isolated PRS varies in different studies from 40% to 74%.[18] There are more cases in females, with a male-to-female ratio of 3:2,[16] which is equal to the ratio comparing male and female children with cleft palate.[19]

The most common PRS syndromes are Stickler syndrome (20%–25% of all cases) and velocardiofacial syndrome (15% of all cases). Nager syndrome, spondyloepiphyseal dysplasia congenital, and other recognized syndromes comprise the rest of the syndromic PRS cases.

The severity and persistence of the clinical pathology are probably related to the nature of the insult, as illustrated by the difference in outcome between "syndromic" and "nonsyndromic" micrognathia.[20]

The previously reported incidence of PRS varies from 1 in 2000 to 1 in 30,000 live births.[21] The highest incidence has been

reported for the United States with 1/3120 cases per live birth, followed by Germany with 1/8060, United Kingdom with 1/8500, and Denmark with 1/14,000.[15] The reported differences in the prevalence of PRS at birth are due to the variations of the case definitions and the different time periods of data collection, as well as the different data collection methods.[15]

Prenatal diagnosis or even prediction of severity of PRS has not been established yet.[22]

CLINICAL FEATURES (NEW CLASSIFICATION 2015)

PRS consists of three essential components.

1. Micrognathia or retrognathia
2. Glossoptosis, possibly accompanied by airway obstruction
3. Cleft palate (usually U-shaped, but V-shape also possible)

It should be mentioned that cleft palate does not have a complete penetrance and can only be seen in about 80% of the Pierre Robin patients.[9]

The airway obstruction in PRS requires early and proper management, since it may lead to hypoxia, cor pulmonale, failure to thrive, and cerebral impairment. Generally, syndromic cases are more severe and have worse prognosis than nonsyndromic PRS.

Usually, it is expected that patients with nonsyndromic PRS will show catch-up growth of the mandible.

AIRWAY MANAGEMENT

Airway obstruction due to glossoptosis can occur at or immediately after birth, but may take much longer (up to 3 weeks) to become apparent.[23] Most neonates present with an isolated PRS and not one of the syndromes, which typically present more significant clinical problems, i.e., airway and feeding difficulties. The airway obstruction in PRS is due to the narrowing or complete obstruction of the pharyngeal space by the posteriorly displaced tongue. This airway obstruction could be intermittent. Most of the complications and unfavorable outcomes of PRS are directly related to delayed or inappropriate airway management.[24] Therefore, special vigilance is required, even in patients with only minor defects. Typical clinical signs of upper airway obstruction are increased respiratory effort, stridor, subcostal retractions, and cyanotic or apneic spells. In an otherwise asymptomatic child, choking attacks, cyanosis during feeding, or repeated aspiration events may be due to intermittent airway problems.

Since PRS infants may also have short or collapsing epiglottis, laryngomalacia, and/or segmental tracheal stenosis, nasoendoscopy and bronchoscopy might be necessary to assess the child.

Every child with symptoms of airway obstruction should be nursed prone with the head to one side. The head should be maintained in level position to prevent either glossoptosis or gastroesophageal reflux. Usually, affected children can be successfully fed by mouth in this position.

Persistence of airway difficulties requires further intervention.

Nasopharyngeal tube

The nasopharyngeal airway bypasses the oral pharynx and the obstruction due to the glossoptosis. A regular endotracheal tube, cut to the appropriate length, is inserted by nasal route and securely strapped in place. The nasopharyngeal airway is a very effective, temporary form of airway management within the intensive care unit. Usually, patients with nasopharyngeal tubes in place would not be sent home, as dislodgement of the tube can result in an acute airway obstruction.

Endotracheal tube

Endotracheal intubation serves as a short-term support if the nasopharyngeal airway is not successful or during resuscitation or anesthesia.

Tongue–lip adhesion/glossopexy

Essentially, in this technique, the tongue is sutured to the lower lip. After the child has demonstrated catch-up growth, the tongue–lip adhesion can be released. The efficacy of the tongue–lip adhesion technique remains a controversial issue.

Glossopexy consists of suturing the tongue base to the mandible. Due to the relatively soft consistency of the mandible, a permanent glossopexy is difficult to achieve; therefore, this technique is also controversial.

Tracheostomy

Tracheostomy should be avoided if possible, and it should only be employed if all other techniques fail. It should be performed by an appropriately skilled surgeon who is familiar with infantile airways. Tracheostomy requires closed monitoring but enables oral feeding. It could be removed after the child's airway obstruction has resolved, which usually happens within the first year of life.

Distraction osteogenesis of the mandible

Distraction osteogenesis comprises a relatively new technique. The mandible needs to be cut near the angle of the mandible on both sides. A specialized mechanical device distracts these two portions every day by approximately 1.5–2 mm. Using this technique, the mandible gradually elongates over a period of 2–3 weeks. Timing of performing a mandibular distraction can be in newborns to prevent tracheostomy or at a later stage to remove a tracheostomy tube.

Distraction osteogenesis has been carried out only during the last 5–10 years. Therefore, long-term follow-up results of this promising technique are not available. Nevertheless, the distraction osteogenesis technique should be reserved for severe cases of nonsyndromic Pierre Robin and syndromic PRS, since in most cases of nonsyndromic PRS, physiologic catch-up growth of the mandible occurs.

Tongue positioning and stimulation plate

During the last decade, a new, nonsurgical technique was developed by orthodontists that guarantees, in most cases, a free airway space and treats the hypoplastic mandible causally. Immediately, a palatal plate is produced, similar to the feeding plate for cleft palate newborns, but with a dorsal spur that goes shortly to the epiglottis (Figure 31.1a–c). Sometimes endoscopic control is necessary during positioning to avoid irritation of the epiglottis. To accomplish this, the tongue is positioned anteriorly and the airway is kept patent. Moreover, via functional stimulation of the tongue, the mandible starts to grow during the following months and will be quite normal when the palatal closure is performed at the age of about 6 months (Figure 31.2a–e). Feeding is also supported, but problems remain in some cases.[25]

Noninvasive ventilation

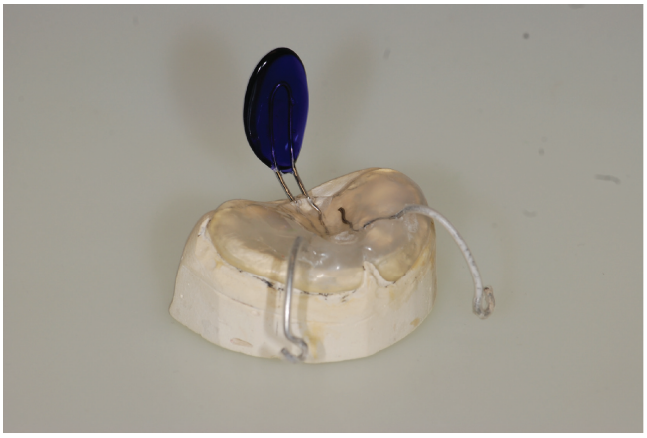
There is growing evidence that noninvasive respiratory support could improve breathing patterns and respiratory outcomes for infants with severe upper airway obstruction due to PRS. Subsequently, the rate of necessary tracheostomies was reduced. Some authors consider this the first line treatment.[26]

NUTRITIONAL MANAGEMENT

Children with PRS have feeding difficulties in 38%–62%.[27] Initial treatment consists of bottle-feeding in a prone position with the head slightly elevated. This method of feeding is appropriate in children with catch-up growth of the mandible.

If this is not satisfactory, gavage or feeding tubes can be used temporarily to improve nutrition. If the feeding is still not successful, the child might need a gastrostomy, which could be removed after gaining the ability to be fed orally.

It has been shown clearly that infants with PRS require adequate caloric intake. It is important to achieve the maximum growth rate of the mandible since the resolution of the airway problems is directly related to mandibular growth. Only recently has increased work of breathing



(a)

(b)

(c)

Figure 31.1 **(a–c)** Stimulation plate.

been appreciated as an important component of calorie consumption. It may be necessary to provide these children with several times the normal caloric requirement of an infant to compensate for up to a 10-fold increase in respiratory work. Indeed, failure to gain weight despite maximum nutritional intake should suggest the need for more aggressive airway management. The availability of total parenteral nutrition should prevent any instances of failure to thrive, but it is rarely needed if other aspects of the condition are managed correctly.

It has been additionally proven that that PSR infants have a higher incidence of gastroesphageal reflux (GER), and even empiric reflux treatment may be indicated to improve breathing and feeding.

CLEFT PALATE

Cleft palate is present in at least 80% of patients with PRS. Cleft palates are typically repaired while patients are infants. A palatal plate can be used in patients with a cleft of the hard palate to improve feeding. The plate also corrects the tongue position by moving it anteriorly. In patients with a cleft of the soft palate alone, a palatal plate has no positive effect on feeding, but it can improve the tongue position and stimulate mandibular growth. To enhance this effect, the plate can be modified by an anterior stimulus according to Castillo-Morales.[28]

Surgical protocols differ from center to center, and cleft closure is performed not only by different techniques (i.e.,

Langenbeck, Furlow, Wardill) but also at different ages, ranging from 4 to 36 months.

It is currently assumed that early surgery will provide a better chance of normal palatal function and speech development.

MICROGNATHIA/RETROGNATHIA

The first described functional therapy for micrognathia was the use of the orthodontic palatal plate to achieve growth stimulation of the mandible. It was not clear until today whether the growth potential of the mandible after this stimulation is sufficient to achieve the normal dimensions. However, it has been shown, based on physical examinations until age 5, that the mandible can barely regain its growth in relation to a normal population.[29] A retrospective longitudinal study by cephalograms and lateral photographs of American patients with PRS and cleft of the soft palate showed that the mandible achieved only partial catch-up growth and, in adults, a smaller maxilla, mandible, and a narrow respiratory airway space persisted.[30] Studies in the Finnish population showed the same result.[31] An increased mandibular growth was seen during the first 2 years of life, but normal craniofacial dimensions were never achieved. At the young adult stage, even if the patient's profile appeared less retrognathic due to masking by the overlying soft tissues or the patient's teeth showed neutral occlusion, cephalograms revealed retrognathia and caudal–dorsal rotation of the mandible. Thus, it seems in accordance with today's knowledge that the microgenia in PRS can be balanced only partially by growth processes. Frequently, orthodontic therapy is necessary in childhood. In severe cases, surgical advancement of the mandible combined with a genioplasty can be beneficial, as well.

SKELETAL ANOMALIES

Around 11%–21% of children with PRS have limb defects.[18] Common anomalies are talipes equinovarus, syndactyly, short or absent digits, and hypoplastic long bones. Occipito-atlanto-axial instability has also been described, emphasizing the need for very experienced clinicians to undertake the intubation of such patients. Orthopedic and radiological consultation should be sought in children with suspected skeletal problems. Rare neuromuscular defects can also occur, resulting in a tendency for glossoptosis to persist despite mandibular growth.[11]

EAR PROBLEMS

Malformations of the ear have a frequency of 10.5% and consist of defects in the auditory capacity and anomalies of the shape of the ear. One main concern is the frequently recurring infections of the middle ear, which also occur in patients with a cleft palate and are based on disturbed function of the Eustachian tube. Therefore, a hearing screening has to be performed at birth. At a later date, control of the middle ear tube function has to be achieved and grommets placed, if necessary.[32]

CARDIOVASCULAR ANOMALIES

Intrinsic cardiac defects are found in up to 20% of infants with PRS.[33] Septal defects are common, but more complex lesions can also occur. A thorough cardiovascular examination should be performed in PRS babies, particularly since airway difficulties may aggravate the cardiac status.[34]

OCULAR ANOMALIES

Retinal detachment and micrognathia occur as part of Stickler syndrome,[35] but 10% of infants with nonsyndromic PRS also have eye defects, such as strabismus, ptosis, and microphthalmia. More severe defects such as cataract and congenital glaucoma have also been reported, and ophthalmologic consultation is recommended in all cases.[36]

NASAL OBSTRUCTION

Choanal atresia is a rare accompaniment of PRS,[37] but it may complicate the respiratory difficulties in small infants who do not mouth-breathe. It is important to ensure nasal patency, especially if one nostril is to be utilized for a nasogastric feeding tube. Choanal obstruction by itself can lead to glossoptosis, with consequences identical to those of PRS.[38]

CONCLUSION AND FUTURE DIRECTIONS

In isolated PRS, the long-term outcome is directly related to the quality of the management at the onset of symptoms. With adequate nutrition, mandibular growth will achieve normal or near-normal proportions, and the glossoptosis will resolve. To date, nonsurgical treatment is preferred for infants with PRS.[39]

The previously documented high incidence of mental retardation in PRS patients was almost certainly due to unrecognized episodes of hypoxia, and with good airway management, this complication is uncommon.

Undiagnosed hypoxia may also lead to pulmonary vasoconstriction, with resultant pulmonary hypertension and cor pulmonale. Some instances of sudden death in PRS were likely due to this problem. The presence of cardiomegaly on a chest x-ray should alert the physician to the possibility that hypoxic episodes have been overlooked, and appropriate steps should be taken immediately.

Although airway patency improves with growth, there remains a potential for obstruction, particularly after invasive procedures such as intubation or cleft palate repair.[40] In some children, obstruction may occur during sleep, causing occasional apnea with potentially hazardous consequences.[41] A degree of mandibular hypoplasia may persist for several years, resulting in malocclusion and the need for dental treatment.[42]

The overall mortality rate in infants with PRS is approximately 25%. The majority of deaths occur in children with associated anomalies, particularly those with cardiac defects or an underlying syndrome with two or more organ anomalies.[43] These facts must be considered when counselling parents of affected children. With good medical and nursing care, the prognosis for children with isolated PRS should be excellent.[44]

Macroglossia

THAMBIPILLAI SRI PARAN AND GEORGE G. YOUNGSON

INTRODUCTION

Macroglossia (primary form) is defined as a resting tongue that protrudes beyond the teeth, or in the case of the neonate, the alveolar ridge.[1] Pseudomacroglossia arises when the tongue itself is normal but relative protrusion occurs because of a small mandible.[2]

ETIOLOGY

Primary macroglossia can be due to an intralingual lesion such as lymphangioma, hemangioma, dermoid cyst, or hyperplasia associated with systemic disorders such as chromosomal abnormalities, hypothyroidism, amyloidosis, or simply may be idiopathic. Secondary macroglossia is due to a lesion within the oral cavity adjacent to the tongue such as tumor (rhabdomyosarcoma), neurofibromatosis, lingual thyroglossal cyst, lingual thyroid, ranula, or myositis. Macroglossia is one of the most constant features of Beckwith–Wiedemann syndrome, which is characterized by an omphalocele or umbilical hernia, with associated visceromegaly, somatic gigantism or hemihypertrophy, and hypoglycemia.[3] Intraoral and intralingual enteric duplication cysts have been detected in utero.[4–6]

PATHOLOGY

The histological features depend upon the underlying disorder. In addition to the aforementioned conditions, macroglossia can also be found in the triad of intrauterine growth retardation, transient diabetes mellitus, and macroglossia.[7] It is also seen in a number of syndromes including Behmel, Hurler, Laband, and Tollner syndrome.

PRESENTATION

Lymphangioma is the most common cause of macroglossia to present in the neonatal period (Figure 32.1a and b), and prenatal diagnosis by ultrasound is possible when associated with Beckwith–Wiedemann syndrome[8] and some of the intraoral cystic lesions discussed earlier. The physical presentation will be obvious and may also be accompanied by noisy breathing, difficulty feeding, and drooling. When feeding difficulties are profound, then failure to thrive and poor weight gain will be evident. Macroglossia secondary to lymphangioma may lead to verrucous lesions on the surface of the tongue, and these can ulcerate and exude a serous discharge.

If unrecognized or untreated in the neonatal period, the lesion may become more problematic in infancy or later in childhood, when it may present with minor trauma, e.g., to a lingual lymphangioma. This can then result in intralesional hemorrhage and/or sepsis (usually cellulitis from group B hemolytic S*treptococcus*). In this event, abrupt enlargement may compromise the airway and produce a life-threatening emergency, necessitating tracheostomy and gastrostomy until definitive tongue reduction can be carried out (Figure 32.2).

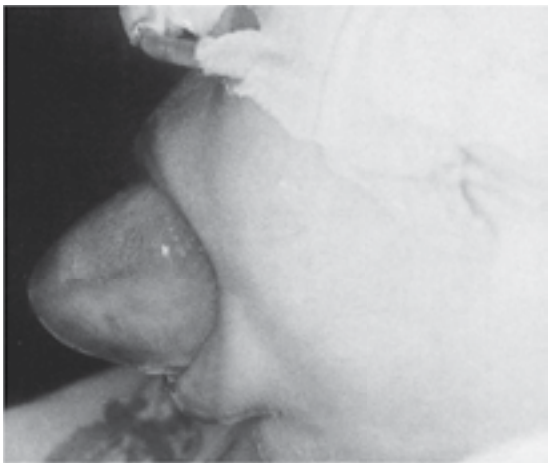
If treatment is inappropriately delayed, protracted dental defects develop, including prognathism, anterior open bite, and an increased angle between the ramus and body of the mandible.[9] Speech defects occur, and articulation is subsequently defective, especially expression of consonants, which are precluded by inadequate tongue movement as a consequence of the increased bulk in a limited cavity. Regression of macroglossia is not a regular feature when due to lymphangioma, and a conservative approach to the lesion has little merit.

DIAGNOSIS

Investigation, following thorough physical examination for secondary causes of macroglossia, comprises thyroid function testing, echocardiography, and karyotype analysis. Magnetic resonance imaging to detail the extent of tongue involvement is indicated particularly when the volume of lingual tissue affected is not clinically apparent.

MANAGEMENT

Mild macroglossia as seen in most children with Beckwith–Wiedemann syndrome and smaller oral lesions does not need any special care. When associated with systemic disorders such as hypothyroidism, management of the primary



(a)

(b)

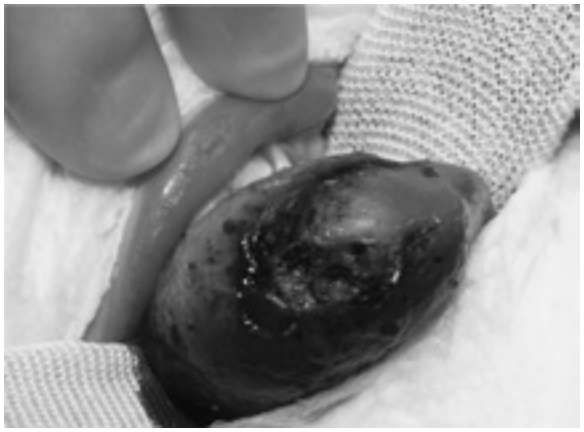

Figure 32.2 Intralesional hemorrhage into a lingual lymphangioma producing respiratory obstruction.

condition alone is what is needed. Moderate enlargements can be managed by nursing the infant in the lateral or prone position to assist the airway and drooling. A multidisciplinary approach including a dietician, speech therapist, and pediatric dentist will be useful.

However, when severe macroglossia with airway compromise is present, early involvement of an anesthetist or intensivist and otolaryngologist is necessary. The airway may have to be secured by a tracheostomy and feeding commenced via a formal gastrostomy. Biopsy is rarely indicated, with histology becoming available on the resected specimen. Needle aspiration of intralingual cystic lesions, however, may be a useful temporizing procedure[5] but requires confident exclusion of vascular anomalies by prenatal or postnatal imaging.

Intravascular photocoagulation[10] and embolism of vascular tongue anomalies[11] are useful in the management of some children. Steroid treatment may confer temporary benefit during an acute airway obstruction early in life. Glossitis and/or sepsis from tongue lesions is seen later in life and will need penicillin-based antibiotic treatment. Surgery with glossectomy, preferably before 7 months of age, confers optimal opportunity for rehabilitation of tongue movement and will avoid complications such as glossitis, hemorrhage, and secondary speech and maxillofacial abnormalities.[12] However, surgery is best avoided during the newborn period in order to minimize unnecessary morbidity.

SURGERY

Reduction glossectomy is the mainstay of treatment, and options include central wedge resection, circumferential wedge resection, or a combined transoral and transcervical approach for a massive infiltrative lymphangioma.[13]

The aims of reduction are to allow intraoral position of the tongue in the floor of the mouth, to restore normal tongue movement, and to permit speech and deglutition. Implicit in these objectives is the fact that surgery should be conservative and a repeat tapering procedure is preferable to removal of excess tissue. The principles involve careful hemostasis by use of a tourniquet or, alternatively, by use of an yttrium aluminium garnet (YAG) laser, CO_2 laser,[14] or harmonic scalpel. We recommend a V-shaped resection of the anterior tongue as has been previously described.[15,16]

Nasal intubation or tracheostomy secures airway protection. The head is placed in a silicone ring and the neck extended. A suture placed on the apex of the tongue and two hemostatic/traction sutures tied over silicone rubber dams at the base of the tongue provide the requisite traction (Figure 32.3). Traction on these three sutures delivers the necessary exposure and hemostasis sufficient for central wedge resection. The resection should not usually extend into the posterior one-third, where the extrinsic muscles of the tongue are inserted. The lateral margins of the incision extend from the level of the anterior gum, with the tongue in a resting position, to the apex, and this incision is beveled such that more ventral than dorsal tissue is removed. This re-creates the natural concavity of the central tongue (Figure 32.4). A straight needle is a useful adjunct to creating this bevel.

The divided lingual arteries are ligated. Restoration of the tongue flaps at the midline is performed incorporating mucosa and a few millimeter of muscle (Figure 32.5).

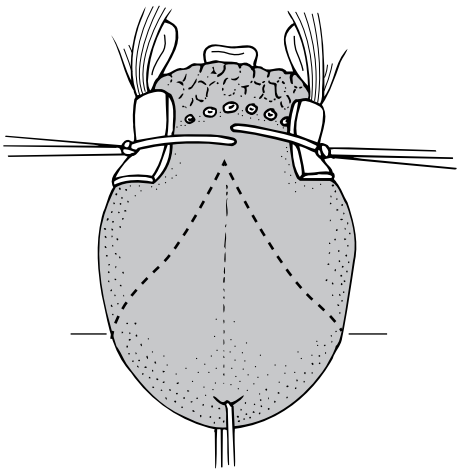

Figure 32.3 Traction sutures allow good exposure and good hemostasis during reduction glossectomy.

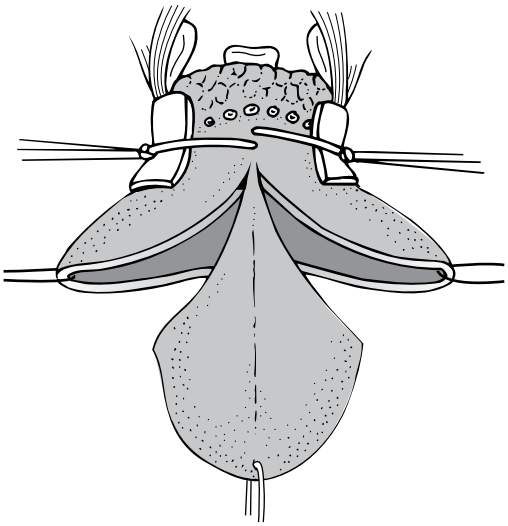

Figure 32.4 Wedge of tissue incorporating more of the dorsal than the ventral aspect of the tongue is removed.

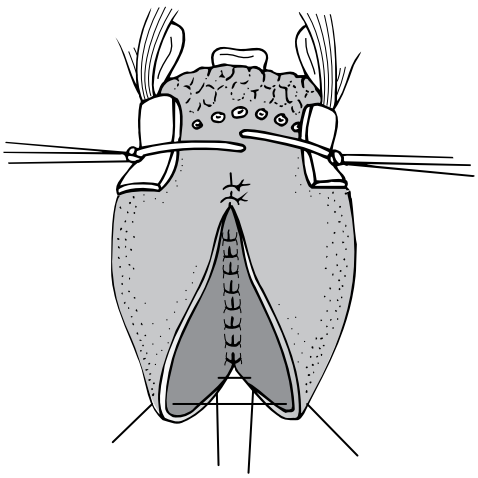

Figure 32.5 The remaining lateral segments of the tongue approximated in the midline.

The opportunity to place a percutaneous gastrostomy should be taken if protracted delay in feeding is anticipated. Antibiotics should be continued into the postoperative period to provide prophylaxis against sepsis in the floor of the mouth. Oral hygiene is maintained with chlorhexidine or saline oral toilet. The appropriate tracheostomy care, if required, is given and secondary orthodontic and speech therapy follow-up arranged.

Tracheostomy in infants

JEYANTHI KULASEGARAH, THOM LOBE, AND JOHN D. RUSSELL

INTRODUCTION

The indications for tracheostomy have changed over time owing to advancements in treatment and technology. In the early 1980s, many tracheostomies were performed as a result of upper airway infection.[1] With the introduction of vaccines against *Haemophilus influenza* and *Corynebacterium diphteriae* and improvements in intensive care units (ICUs) in the 1980s and 1990s, the number of tracheostomies required for infectious diseases has decreased.[2] Several series have documented the changing indications for tracheostomy in children over the past decade. Also, there are regional differences in tracheostomy indications. In the United Kingdom, three large series[3–5] have reported long-term ventilation as the most common indication for tracheostomies. Research from France,[6] Singapore,[7] and Spain[8] also reports a greater number of tracheostomies being done for ventilator dependency. However, some centers have reported a reversal back to upper airway obstruction as the most common indication, although it is most often owing to acquired or congenital causes rather than infection. Mahadevan and colleagues[9] from New Zealand published their experience from 1987 to 2003 and found that upper airway obstruction was the most common indication for tracheostomy. More recent studies from United States,[10] Canada,[11] and Switzerland[12] have also found upper airway obstruction as the most common indication.

This chapter will discuss the indications, techniques for insertion, and maintenance of a tracheostomy in infants.

INDICATIONS FOR TRACHEOSTOMY

The indications for tracheostomy in neonates and infants can be broadly divided into three categories: (1) prolonged ventilation, (2) upper airway obstruction (congenital or acquired), and (3) pulmonary toilet for mainly neurological patients with aspiration (Table 33.1).[2,6,9,12,13]

Tracheostomy is recommended for patients requiring extended periods of ventilation to manage lung disease, such as bronchopulmonary dysplasia in premature infants, as well as to manage respiratory failure directly or indirectly, as a result of congenital neurologic, pulmonary and cardiovascular abnormalities. There has also been a trend toward patients with significantly complex medical problems surviving long term, and these patients often require long-term ventilation via a tracheostomy.[3,4]

Airway obstruction, caused by congenital or acquired lesions, can lead to insertion of tracheostomy. The immature airway manifests itself as laryngomalacia, tracheomalacia, or a combination of the two conditions. Patients with a congenitally stenotic airway or tracheal agenesis are special cases. In the case of agenesis, an emergency tracheostomy may be necessary where the trachea reestablishes distally. Usually, however, these patients can be ventilated best using a mask because the bronchi come off the esophagus and an esophageal tube can cause obstruction. Technology today allows bedside bronchoscopy in such infants with tenuous airway status so that proper decisions can be made before one risks transporting the infant to the operating theatre.

Occasionally the management of a tumor such as a cervical teratoma or sarcoma in infancy will mandate a tracheostomy. More likely, a hemangioma or lymphangioma will compromise the airway to the extent that a more stable airway is needed. Infants with congenital high airway obstruction (CHAOS), often are diagnosed in utero today, and an ex utero intrapartum therapy (EXIT) procedure, where a tracheostomy is performed with maternal–fetal circulation intact, may be required.[14]

There are several acquired airway conditions that require tracheostomy, including infection, papillomatosis, neuromuscular failure, chronic aspiration, and subglottic stenosis.

Other related conditions are congenital or acquired vocal cord paralysis, which is usually due to a central nervous system deficit; phrenic nerve injury, which may be associated with a difficult delivery; and recurrent laryngeal nerve injury, which may occur after ligation of a patent ductus arteriosus.

Table 33.1 Indications for tracheostomy

Category		Indications
Prolonged ventilation	Respiratory	Bronchopulmonary dysplasia
		Pneumonia
		Restrictive lung disease
	Cardiac	Congenital heart disease
	Neuromuscular disease	Spinal muscular atrophy
		Myasthenia gravis
	Central	Encephalopathy
		Intracranial hemorrhage
		Status epilepticus
		Brainstem tumors
		Guillain–Barré syndrome
		Ondine syndrome
		Silvermann syndrome
	Others	Sepsis
		Trauma
Upper airway obstruction	Craniofacial anomalies	Mandibular hypoplasia
		Pierre Robin
		Crouzon syndrome
		CHARGE syndrome
		Treacher Collins
		Apert syndrome
		Freeman–Sheldon syndrome
	Nose/postnasal space	Choanal atresia/stenosis
	Larynx	Laryngeal atresia
		Laryngeal cleft
		Laryngeal stenosis
		Subglottic stenosis
	Trachea/bronchus	Tracheomalacia/bronchomalacia
		Tracheal stenosis
		Tracheal atresia
	Bilateral vocal cord paralysis	Congenital
		Arnold–Chiari malformation
		Brain tumor
		Prolonged intubation
	Tumor (airway/neck)	Giant cervical teratoma
		Laryngotracheal hemangioma
		Cervicofacial hemangioma
		Lymphangioma
	Trauma	Cranial/neck/vertebrae
Pulmonary toilet	Neurological patients with aspiration	
	Chronic aspiration syndrome

Note: CHARGE-Coloboma of the eye, heart defects, atresia of the nasal choanae, retardation of growth and/or development, genital and urinary abnormalities, ear abnormalities and deafness.

Some patients with craniofacial anomalies, such as choanal atresia and Pierre Robin syndrome, may require a tracheostomy.

Rarely, trauma will prompt the surgeon to perform a tracheostomy. This can be related to birth trauma, child abuse, burns, or accidents.

Majority of patients requiring a tracheostomy are under the age of 1, as shown in many series.[3,8,9,11,12]

PREOPERATIVE EVALUATION

Although originally, tracheostomy was developed as an emergency procedure for acute airway difficulties, in many settings, most infants who need a tracheostomy already have an endotracheal tube in place. Infants will require direct laryngoscopy and bronchoscopy to assess the airway.

Following an airway assessment of neonates and infants, especially patients in the neonatal intensive care unit (NICU) with complex malformations, extreme prematurity, complex syndromes, cardiac anomalies, or neurological deficit, a multidisciplinary team (MDT) consisting of a pediatric otolaryngologist, a pulmonologist, a neonatologist, an intensivist, pediatric surgeons, cardiothoracic surgeons, a neurologist, a tracheostomy nurse specialist, a speech and language therapist, and a dietician should meet and discuss the clinical situation and make appropriate recommendations to parents or caretakers prior to proceeding with tracheostomy. The MDT also gives an opportunity for family and caretakers to discuss the risks and benefits of the procedure, how the procedure is performed, and short- and long-term goals for the patient. A growing body of literature has demonstrated that an MDT approach gives the best results in terms of clinical outcome for the patients and cost effectiveness for the National Health Care System.[15,16]

When an infant is not intubated, but is under consideration for tracheostomy, the extent to which the child maintains oxygenation and demonstrates adequate ventilation as judged by the PCO_2 measured by transcutaneous monitoring will determine the need for a more direct assessment before a decision for tracheostomy is made.

The surgeon should make certain of the coagulation status, hemoglobin level, and electrolytes as indicated by the patient's condition. The nutritional status of the patient should also be taken into consideration. Poor nutrition will complicate nearly any condition in infancy and may weigh in favor of an earlier tracheostomy than would be indicated otherwise. Finally, patients with persistent aspiration, despite correction of any gastroesophageal reflux, may necessitate a tracheostomy to prevent severe pulmonary consequences.

Choosing the appropriate tube size is the key element when planning for tracheostomy. An extensive selection of neonatal and pediatric tracheostomy tubes are currently available, produced in response to a variety of specific clinical requirements.[17] The optimal size of the tracheostomy depends on the clinical indication for the procedure, the size of the airway, and the age of the patient. The size designations of pediatric tracheostomy tubes are based on the inner diameter (ID). Neonatal tubes are similar to pediatric tubes in their ID and outer diameter (OD) but shorter in length.

There are several ways to determine the appropriate tracheostomy tube to be used. Tweedie and colleagues[17] at Great Ormond Street Hospital for Children in London have produced a sizing chart as a guide to determine appropriate tube selection prior to tracheostomy. Behl and Watt,[18] on the other hand, developed a simplified formula to calculate tracheostomy tube size from the age of the child, as follows:

$$\text{ID (mm)} = (\text{Age}/3) + 3.5$$

$$\text{OD (mm)} = (\text{Age}/3) + 5.5$$

The ID and OD of the tracheostomy tube also correlates well with patient weight, as follows[18]:

$$\text{ID (mm)} = [\text{Weight (kg)} \times 0.08] + 3.1$$

$$\text{OD (mm)} = [\text{Weight (kg)} \times 0.1] + 4.7$$

TECHNIQUE

The infant is placed supine on the operating table, sufficiently toward the head of the table so that the surgeon can access the infant's neck easily and also the anesthesiologist can gain access to the patient to manipulate the endotracheal tube when required during the procedure.

These cases should be done under a general anesthetic unless the infant is so ill as to be unable to tolerate the drugs. Even so, an anesthesiologist should maintain control of the airway while the surgeon is exposing and manipulating the trachea.

The patient's cardiorespiratory status should be monitored during the case. This should consist of a cardiac monitor for heart rate, a blood pressure monitor, and ideally, a pulse oximeter to assess the infant's oxygenation. A rigid bronchoscope should be available throughout the procedure, in case there is any need to manipulate and control the airway.

If the infant has not had prior laryngoscopy and bronchoscopy, a diagnostic examination is performed prior to tracheostomy to confirm the diagnosis and to assure that the tracheal lumen will accept a tracheostomy without difficulty. Special issues, such as a tracheostomy to stent an airway for severe tracheomalacia, can be assessed by bronchoscopy to determine the proper length of the proposed cannula, which may have to be specially ordered. In some cases, it may be necessary to use an ordinary endotracheal tube placed through the cervical incision and secured to the skin of the neck until this temporary tracheostomy cannula can be replaced with the specially ordered device.

When positioning the infant on the operating table, the neck should be extended sufficiently to allow complete access to the neck. Sometimes, in chubby infants, it is still difficult to see the entire neck, despite best attempts. A roll should be placed under the infant's shoulders to facilitate proper positioning (Figure 33.1).

The endotracheal tube should be secured so that the anesthesiologist can easily remove the tube at the appropriate time. This means that any tape should be loosened beforehand. If there is a feeding tube in place, it should be removed so that it does not interfere with endotracheal tube manipulation.

When the infant is properly positioned and monitored, the entire neck from the lower lip to below the nipples should be prepped with a suitable surgical prep and draped. The superior most surgical drape should allow easy access to the patient by the anesthesiologist.

Once prepped and draped, the surgeon should carefully palpate the infant's neck to locate the trachea that hopefully is in the midline. The surgeon must remember that the infant's trachea is quite mobile and compressible, and may be difficult to palpate. The anesthesiologist can jiggle the endotracheal tube from above to assist with its location.

A transverse skin incision is best. We make our incision in the lower neck crease, about the width of one finger above the jugular notch. If the incision is too low, you will end up in the mediastinum, and the cannula will be placed too low in the trachea. We first score the skin with a scalpel and then use a bipolar diathermy (electrocautery) device to deepen the incision, taking care not to burn the skin. This incision is extended through the subcutaneous fascia and platysma muscle, which is quite thin in the small infant. A pad of subcutaneous fat is excised. This shortens the tracheostomy tract and allows immediate exposure of the strap muscles. It is helpful to insert two right-angled retractors in the corners of this incision to better expose the operative site.

Next, we use two atraumatic forceps to grasp the anterior cervical fascia on either side of the midline and open it vertically in the midline. We extend this incision inferiorly to the jugular notch and superiorly to the thyroid gland.

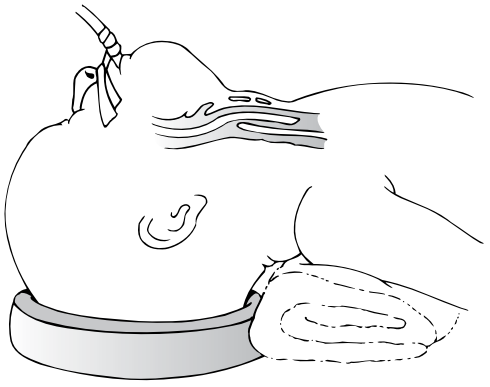

Figure 33.1 Position of infant for tracheostomy. The shoulders are elevated on a roll; the head is hyperextended on the neck and supported by a doughnut-form support.

The strap muscles, immediately beneath the anterior cervical fascia, similarly are separated in the midline. Usually, there are few to no blood vessels in the dissection thus far. Occasionally, the surgeon will encounter a few small vessels that cross the midline. These should be cauterized and divided as they are encountered.

Once these muscles are separated, we place the two retractors deep into the muscle edges and gently retract laterally to better expose the trachea below. Sometimes it is necessary to free the muscle edges sufficiently to allow room for the blade of the retractor to gain a secure purchase. The trachea should be visualized easily. If not, then palpation in the wound with manipulation of the endotracheal tube by the anesthesiologist will help locate the trachea.

The proposed tracheostomy cannula should be selected and opened and its OD visually checked against the exposed trachea to judge the correctness of its size. If it seems that the initial selection was incorrect, then a tracheostomy cannula of a more appropriate size should be selected.

The pretracheal fascia should be lightly scored with the cautery to coagulate any tiny vessels on the surface of the trachea in the midline. Again, the blades of the retractors should be deep in the wound on either side of the trachea for optimal exposure.

A suture of 4-0 Prolene or its equivalent should be placed on either side of the midline scored anterior trachea (Figure 33.2). Each suture incorporates one or two tracheal rings. These sutures are not tied onto the tracheal wall, but can be tied at their ends and should be left 6–8 cm in length. At the end of the case, these sutures should be taped securely to the anterior chest wall and used to locate the tracheal incision in the event of a postoperative emergency in which the newly placed tracheostomy cannula dislodges. These sutures also can be used to hold open the edges of the

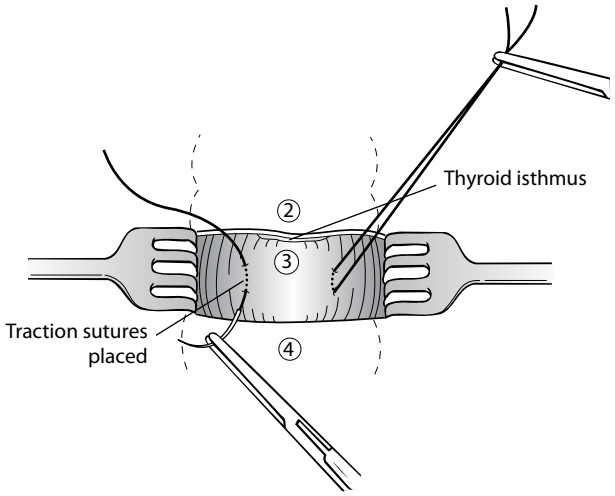

Figure 33.2 Traction sutures of fine silk are placed around the third tracheal ring to stabilize the trachea before incision. The sutures are tied in loose loops and later taped to the anterior chest wall. The sutures are left in place for 4 days as a precaution against accidental decannulation postoperatively.

tracheal incision for ease of placement of the tracheostomy cannula at operation.

In most tertiary centers, maturation sutures are used, and this involves the placement of sutures between the anterior tracheal wall and skin, which hastens the formation of a mature stoma and has the potential of decreasing the risk of accidental decannulation and the formation of granulation tissue.[19,20]

The surgeon should request that the endotracheal tube be loosened and prepared for removal. Using a No. 11 blade, a vertical incision is made through the tracheal wall along the score mark (Figure 33.3). Two or three tracheal rings should be divided, usually rings 2, 3, and 4. Rarely, it is necessary to divide the isthmus of the thyroid gland for proper tracheostomy positioning. In some centers, a transverse tracheal incision is used instead of a vertical incision.[21] Removal of a tracheal ring is likely to result in a tracheal deformity and thus should be avoided. Similarly, unless one is dealing specifically with a localized stenosis or deformity, tracheal wall resection is to be avoided.

Suction should be available in case blood or secretions interfere with the surgeon's view of the tracheal lumen. The tip of the cannula to be inserted should be lubricated with a water-soluble surgical lubricant and positioned over the incision, poised for insertion when the endotracheal tube is withdrawn.

The surgeon should then ask the anesthesiologist to withdraw the endotracheal tube sufficiently to clear the lumen so that the tracheostomy cannula can be inserted and directed caudally toward the carina.

One way to avoid misplacement is to insert a suction catheter through the lumen, beyond the tip of the cannula (Figure 33.4). The suction catheter then can be inserted into

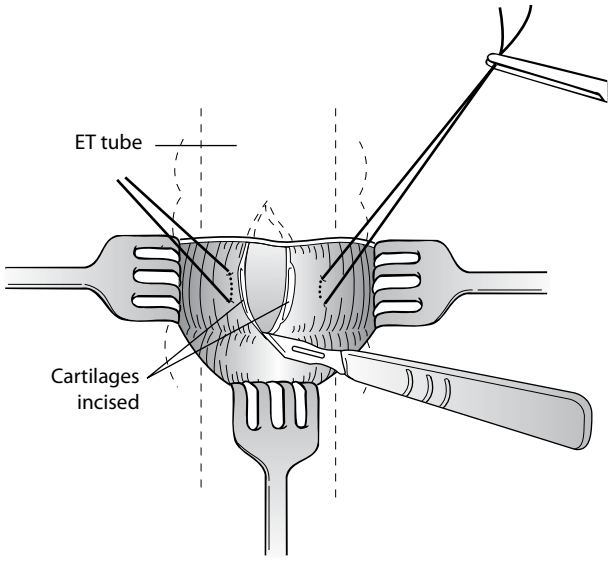

Figure 33.3 The trachea should be opened through a midline vertical incision across 2–3 tracheal rings. The incision must be long enough to avoid excess tube pressure against the cartilages. A tight tube can result in pressure deformity and reabsorption of cartilage. ET, endotracheal tube.

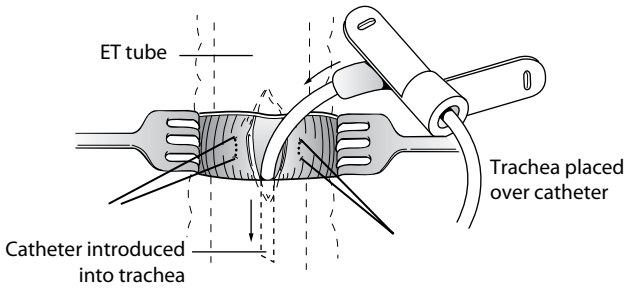

Figure 33.4 Tube insertion into the trachea is accomplished by shifting the endotracheal tube up to the cephalic margin of the new stoma, inserting a tracheal suction catheter into the trachea through the newly established opening, and then advancing the tracheostomy tube over the catheter in the trachea. This is safer than using the tube obturator, the short tip of which sometimes slips out of the stoma and allows the tracheostomy tube to pass anterior to the trachea and into the mediastinum. ET, endotracheal tube.

the tracheal lumen first and serve as a guide over which the cannula can be passed. This technique also is useful should the cannula become dislodged after the procedure.

If, for any reason, the tracheostomy cannula does not fit easily into the trachea, it should be removed and the endotracheal tube advanced beyond the tracheal incision so that ventilation will not be compromised. This might occur if the diameter of the tracheal lumen has been overestimated and the previously selected tracheostomy is too large to fit into the trachea. In the latter case, a smaller cannula should be selected.

As soon as the cannula is in place, the obturator or suction catheter should be removed, and the anesthesiologist should disconnect the ventilator hose from the endotracheal tube and connect it to the tracheostomy cannula. Once that is done, the anesthesiologist should administer several deep breaths to the patient to confirm that the cannula is in the proper place by auscultation of the lungs and that the infant can be ventilated satisfactorily. A flexible bronchoscope is used to confirm the position of the tracheostomy tube. If it appears that although the cannula width is appropriate, it is too long and its tip rests on the carina, then a shorter neonatal tube should be used instead of a pediatric tube. Once adequate ventilation is confirmed, then the endotracheal tube can be removed completely.

Once the cannula is connected to the ventilator, the cervical wings of the body of the cannula need to be secured to the patient. We don't rely on a tie placed around the neck, but accomplish this with the aid of sutures.

For each wing, a suture of 3-0 silk or its equivalent is passed through the skin of the neck, then through the upper edge of the wing of the cannula (midway between the midline and the end of the wing), through the lower edge of the wing, and then again through the skin. When this suture is tied, the skin will be drawn over the wing and usually will cover it. After these sutures are placed, both wings will be securely fixed to the skin of the neck.

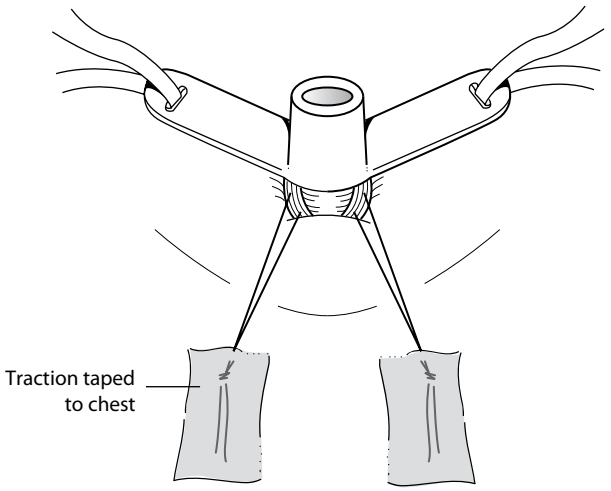

Figure 33.5 Prevention of accidental decannulation is the surgeon's responsibility. The tube should be taped to the anterior chest for 4 days in case an unexpected tube change should become necessary.

The two ties that were placed in the anterior tracheal wall should now be taped securely to the anterior chest wall in such a fashion that ensures that their ends are easily accessible in case they are needed in an emergency to reinsert the cannula (Figure 33.5).

Finally, the cotton tape or tie that usually comes with the cannula is passed through the holes in the end of the wings and tied around the neck to further secure the cannula. This should be tied in the back of the neck. Simple gauze dressing with antibiotic ointment applied is placed underneath the wings of the cannula over the cervical incision to complete the procedure.

We send our infants to the ICU after a fresh tracheostomy in case of emergency.

PERIOPERATIVE MANAGEMENT

If the skin of the patient's neck is infected with a bacterial or fungal infection, this should be cleared before any operation is undertaken unless emergency tracheostomy is required to save an infant's life.

In patients with short, fat necks, it may be necessary to place the infant in a position of neck extension to facilitate clearing any skin infection or breakdown that is due to chronic moisture. Simply exposing the infant's neck to air for drying often is sufficient to clear any problem.

Immediately after the tracheostomy is secured, the roll under the patient's neck should be removed, and a radiograph of the chest should be reviewed before the patient is transferred to the ICU. This is important to make certain that the tip of the cannula is sufficiently clear of the carina and will not become obstructed as the patient's neck is manipulated.

A bed-head notice completed by the ear, nose, and throat (ENT) surgeon or the tracheostomy nurse specialist must be placed on the patients' cot or bed, with details of the type and size of tracheostomy tube used, size and depth of suction catheter appropriate for the tube, any airway problems noted at laryngoscopy, and date of estimated first tube change.

The fresh tracheostomy should be left in place until the first tube change, which varies in different centers anywhere from 3 to 7 days.[22,23] At least once a day, the site should be cleaned using aseptic technique with gauze dampened in a solution of 0.9% normal saline.

Adequate humidification is mandatory to prevent crusting within the tracheostomy tube, as is gentle suctioning using the appropriate-sized suction catheter and adhering to precise depth measurement to prevent trauma to the tracheal mucosa. Suction catheters have numbered graduations for accurate insertion lengths.

The sutures securing the tracheostomy should be left untouched until the first tube change. The surgeon does the first tracheostomy tube change with the tracheostomy nurse specialist. The sutures to the edges of the tracheal incision should also be left until the first tube change.

If the patient is unusually agitated or the ventilator tubing is so heavy that dislodging the cannula is highly likely, then sedation or paralysis may be helpful until the wound has matured and reinsertion can be done more safely.

After the cannula is free and the cotton neck tape is untied, the cannula can be removed and replaced. If a temporary endotracheal tube is being replaced with a specially ordered tracheostomy cannula, the new cannula should be inserted as described earlier.

HOME INSTRUCTION AND CARE

Patients should be discharged home with an emergency case containing essential equipment (spare tracheostomy tubes, Ambu bag) and supplies required in case of accidental decannulation or for emergency tube change, and this case accompanies the child at all times. Parents and caretakers are taught basic life support (BLS) or cardiopulmonary resuscitation (CPR) prior to discharge. They should be familiar with emergency algorithms, mainly for blocked tube and when the tracheostomy tube cannot be replaced.

The tracheostomy tube is held in place with cotton tapes around the neck, and it is changed on a daily basis or twice daily when required. Two people are required to change the cotton tapes to prevent accidental decannulation. Parents and caretakers are trained prior to discharge not only on how to change the tube holder but also on how to clean the stoma and neck. It is important to ensure the skin around the tracheostomy tube and neck is not traumatized.

Precise suctioning is crucial in pediatric tracheostomy care and is only recommended when there are clear indications that the patency or ventilation of the patient is compromised. Parents or caretakers are sent home with a suction machine and are taught suction technique. They should also know how to use an Ambu bag for ventilation in conjunction with suctioning.

An air filter and humidification device, either heat moisture exchange (HME) or Swedish nose of appropriate size, should be attached to the tracheostomy cannula if a ventilating device or some other humidification device is not connected. Of course, the family or caretakers must know how to use and troubleshoot in case of problems with using any of the devices chosen, especially the cannula and its attachments.

Tracheostomy tube change is only performed by trained and competent staff[24] and is planned on a weekly or monthly basis depending on the type of tube used.

It is often helpful to arrange for home nursing visits until the family becomes familiar and comfortable with the new devices; this is especially true when it comes time for the first scheduled tracheostomy change if it is to be done at home.

COMPLICATIONS

The potential complications of tracheostomy are listed in Table 33.2. Pediatric patients have a higher reported morbidity and mortality rate, particularly preterm infants, compared to the adult population.[25,26] Published rates of complications range from 19% to 57% in several case series, with overall mortality rate attributed to underlying medical condition ranging from 10% to 21%, and tracheostomy related mortality was 0.9%–3.2%.[2,3,6,8,9,11,12,26]

Pneumothorax is a potential intraoperative complication because in infants, the apex of the lung extends into the root of the neck, and this can be violated if the surgeon fails to stay in the midline of the neck during the procedure.

Hemorrhage is an unusual complication that can occur at the time of operation or as a delayed event. When hemorrhage occurs at operation, it can be controlled easily with electrocautery or vessel ligation. Rarely, especially in the smaller newborn, the thyroid gland is near the incision site on the anterior trachea and is inadvertently divided or lacerated. The resultant hemorrhage usually can be controlled with sutures or electrocautery.

Late hemorrhage often is more problematic and can be more serious. First, it must be ascertained whether the hemorrhage is from the tracheal lumen or from the incision. Suctioning the cannula, inspecting the wound, and using a flexible bronchoscope through the tracheostomy tube can accomplish this.

More problematic is the possibility of hemorrhage from one of the great vessels, such as the innominate vein or artery. This can occur from erosion of the vessels when the cannula fits too snugly in the thoracic inlet and partially compresses the vessels against the manubrium or clavicle. This type of hemorrhage often presents with a so-called herald bleed, which starts briskly but stops, and usually requires a trip to the operating room to repair the damaged vessel.

Aside from hemorrhage, the cannula can become dislodged. We are compulsive about securing the cannula in place using the techniques described earlier in order to avoid this complication. Even so, despite our best efforts, a suture will pull loose, or one of the plastic wings will tear, allowing the cannula to dislodge. We prefer to keep our infants in the ICU during the immediate postoperative period. We anticipate that if the cannula becomes dislodged, it will be noticed immediately. Replacing the cannula in the immediate postoperative period can be a treacherous ordeal that, under ideal circumstances, should be done by someone familiar with cannula insertion. If a surgeon or intensivist is readily available, then one of them should replace the cannula and resecure the device.

Injury to the vagus nerves or, more likely, the recurrent laryngeal nerves can occur. In experienced hands with a

Table 33.2 Tracheostomy complications

Complications	
Intraoperative risk	Hemorrhage
	Recurrent laryngeal nerve injury
	Posterior tracheal wall tear
	Pneumothorax
	Esophageal injury
	Inability to ventilate
	Creation of false passage
	Cardiac arrest, death
Early postoperative risk	Accidental decannulation
	Respiratory arrest
	Inability to replace tracheostomy tube
	Stomal breakdown
	Skin erosion
	Ventilation problem
	Stomal bleeding
	Pneumothorax, pneumomediastinum
Long-term risk	Stomal granulation
	Tracheocutaneous fistulae
	Stomal infection/cellulitis
	Subglottic stenosis
	Suprastomal collapse
	Stomal bleeding
	Tracheitis
	Tracheomalacia
	Decannulation
	Tube occlusion

surgeon well versed in the anatomy of the infant's neck, this injury should be rare.

While unlikely, it is possible to place the cannula into the esophagus. This can occur if the trachea is retracted laterally, out of the field, and the esophagus is entered in error. If this occurs, the esophagus should be repaired primarily, and a drain should be left in place. The tracheostomy cannula can then be inserted properly.

Infection is an unusual complication and should be treated with the appropriate antimicrobials according to culture results.

Endotracheal granulation tissue can result from the chronic irritation of the tip of the tracheostomy cannula against the tracheal wall or from the repeated suctioning of the trachea. It is common for granulation tissue to develop at the stoma. This can be exophytic at the level of the skin or can be intraluminal. The exophytic granulation tissue at the skin should be cauterized with silver nitrate during an outpatient visit. This may need to be carried out every month or so if bothersome hemorrhage or chronic irritation with infection is present.

If the granulation tissue develops immediately within the trachea at the stoma, it usually can be left alone until it is time for decannulation. Only if the granulation tissue is so bulky that it interferes with routine tracheostomy changes or causes significant hemorrhage should it be removed before decannulation is contemplated.

The development of granulation tissue at the tip of the cannula can present with obstruction, sometimes resulting in a "ball-valve" effect, with trapped air and difficulty with ventilation. This can be diagnosed by slipping a flexible bronchoscope through the cannula to visualize the tracheal lumen beyond the tip of the cannula. If the results of this diagnostic maneuver are unclear, rigid bronchoscopy may be necessary.

Tracheostomy tube obstruction can be prevented with appropriate tube care. This is a more common problem among premature and newborn babies, with a rate of up to 72%, and less frequently in children 1 year and older, with a rate of up to 14%.[13] Suprastomal collapse, tracheal stenosis, and tracheomalacia are other potential long-term complications of tracheostomy. Prior to decannulation, patients should have an airway assessment to rule out these potential complications. If a tracheostomy tube has been in place for a prolonged period of time, following decannulation, there is a risk the stoma does not close completely, leaving a tracheocutaneous fistula. This can be surgically closed after waiting a suitable amount of time.

SPECIAL SITUATIONS

Occasionally, there exist special circumstances that require careful thought and planning. Such is the case with tracheal stenosis. Simple acquired subglottic stenosis can be easily managed with a tracheostomy inserted as described except for the size of the endotracheal tube. A small endotracheal tube may be difficult to palpate, however; thus, locating the trachea may be difficult.

With a particularly stenotic airway, mask ventilation may be the only way to maintain ventilation. The most difficult part of the case is locating the trachea without an endotracheal tube.

For patients with distal tracheal stenosis, tracheostomy insertion may be inappropriate. While beyond the scope of this discussion, the infant should be carefully studied if this diagnosis is suspected. Usually, plain radiographs of the chest may lead one to suspect the diagnosis. Computerized tomography or bronchoscopy may be required for confirmation. When the distal trachea is stenotic in an infant who is difficult to ventilate, a conventional tracheostomy cannula is inappropriate and may interfere with tracheal reconstruction.

Patients who are candidates for congenital heart surgery and in whom the ultimate need for a tracheostomy is anticipated may be best managed by completing the cardiac surgery before tracheostomy is performed. Otherwise, the sternal incision is so close to the tracheostomy site that the risk of cardiac infection is greatly increased.

DECANNULATION

Decannulation usually is anticipated well in advance. Its timing depends largely on the indication for the tracheostomy. Decannulation is considered for the following:

1. Resolution of underlying airway abnormality
2. Natural expansion of the airway with growth
3. Surgical procedures designed to open narrowed airways

There are slight variations in decannulation protocol in different pediatric units around the world, and we use the protocol in Figure 33.6.

Patients with severe subglottic stenoses may have their tracheostomy removed at the time of their laryngotracheal reconstruction or cricotracheal resection. The timing of this procedure, then, depends on the surgeon and may occur any time between 4–6 months and 2 years, or later.

In patients whose tracheostomy was placed because of tracheomalacia, it would be unusual to attempt decannulation before the infant is 1 year of age. The infant should undergo periodic bronchoscopic examination to assess the

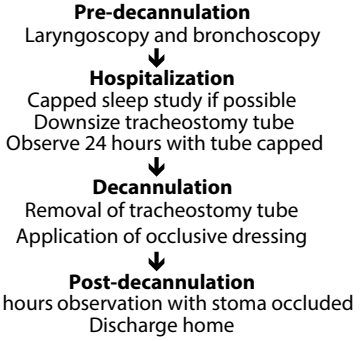

Figure 33.6 Decannulation protocol.

status of the malacia. Once it is certain that the airway is sufficiently mature as to be able to maintain its patency, decannulation can be attempted.

The first step is to make certain that the airway is mature and free of any potential obstructing lesions such as granulation tissue. This is best accomplished with rigid bronchoscopy. Any residual malacia or granulation tissue can be documented and dealt with as needed.

At the time of attempted decannulation, we bring the patient to the operating room, positioned as described earlier for insertion of the cannula with the neck extended, and perform the bronchoscopy. In order to assess whether malacia is present, the patient should not be paralyzed, and the anesthesia should be light. This is to determine whether the airway remains patent, with the patient breathing spontaneously.

Once committed to decannulation, the bronchoscope and neck roll should be removed, and the patient is observed for any difficulty such as severe chest retraction or deoxygenation that would suggest the continued need for the tracheostomy. If, on the other hand, the patient ventilates with ease, then the patient should be fully awakened and allowed to recover in a unit that permits careful observation.

We usually keep these patients in the hospital overnight, or longer if there is any concern, to assure that the tracheostomy is no longer required.

Once the cannula is removed, a snug dressing of plain or petroleum jelly–saturated gauze is secured over the tracheostomy stoma to occlude it. The caretakers or parents should be instructed on how to change this dressing until the stoma closes completely.

Occasionally, we encounter a stoma that does not close spontaneously. If the stoma remains open after several months, then operative closure of the stoma can be performed as an outpatient procedure. Usually, this is simply a matter of excising the stoma and placing a simple stitch or two in the anterior trachea. A larger persistent opening may require an anterior wedge excision for proper repair. This may necessitate admission to the hospital.

If, after the patient leaves the operating room decannulated, he/she becomes fatigued or demonstrates other signs of respiratory distress, the dressing can be removed, and another cannula should be reinserted. A smaller cannula size can be inserted if desired.

This technique often is used to serially wean a patient to progressively smaller-sized cannulas until decannulation is certain to be successful.

If, after decannulation, it is necessary to reinsert a tracheostomy, the procedure should be done in the operating room. While this is usually done with an endotracheal tube in place, there are some patients for whom it may be undesirable to insert an endotracheal tube. This avoids airway irritation and prevents restenosis. That being the case, the surgeon can inject a local anesthetic around the stoma, dilate the stoma with Hegar dilators (or possibly make a small incision with a No. 11 scalpel blade), and reinsert a cannula of an appropriate size. This maneuver should only be attempted if the anesthesiologist can maintain an adequate airway during the procedure.

Reported decannulation failure rates in children range from 5% to 21.4% according to several series.[9,12,28,29]

Congenital cysts and sinuses of the neck

YOUSEF EL-GOHARY, JOSEPH FUSCO, AND GEORGE K. GITTES

INTRODUCTION

Pediatric surgeons frequently encounter cervical masses with intriguing clinical presentations in infants and children. Some can be easily diagnosed with a good history and physical examination, such as the thyroglossal cyst. Others require more extensive investigation and imaging to accurately diagnose and treat. The vast majority are benign in origin; however, rarely, they can be malignant.[1] They frequently form from residual embryologic structures that have failed to resorb completely, or failed to mature. Knowledge of the embryological origins of these cysts and sinuses, along with a detailed knowledge of neck anatomy, is essential for proper management and for successful dissection and excision. Thyroglossal duct cysts are the most congenital neck masses to be encountered in practice, followed by branchial cleft anomalies and dermoid cysts.[2] We will discuss in this chapter the embryology of the neck, followed by a brief review of the common neck cysts and sinuses, along with their management.

EMBRYOLOGY

During early embryonic stages, the primitive gut tube, which is derived from the endodermal germ layer during gastrulation, is divided into the foregut, midgut, and hindgut domains, each of which will give rise to specialized regions due to the regional specification of the gut tube.[3] The foregut, which includes the pharyngeal (branchial) apparatus, extends between the buccopharyngeal membrane and ends at the origin of the liver bud.

The pharyngeal apparatus, which consists of arches, pouches, and clefts, will eventually give rise to the various muscles, nerves, bones, and cartilage in the head and neck region, as illustrated in Figure 34.1 and Table 34.1. There are six pharyngeal (branchial) arches, each consisting of a core of mesoderm, with its own nerve and arterial supply, surrounded by an outer ectodermal and inner endodermal lining. The mesoderm of the second pharyngeal arch proliferates and causes the arch to grow caudally, overlapping the third and fourth arches, and in the process burying the second, third, and fourth pharyngeal clefts and creating a temporary cervical sinus, which normally disappears (illustrated in Figure 34.2). The first pharyngeal cleft will give rise to the external auditory meatus, and the fifth arch disappears. It is the incomplete closure or obliteration of these ectodermal portions of the second, third, and fourth pharyngeal clefts that leads to the various neck anomalies, including cartilaginous remnants, that pediatric surgeons encounter today.[4] The remnants of these clefts form the cervical sinus, which remains connected to the surface via a narrow canal called the "external" branchial fistula, which may drain a branchial cyst. Rarely does the branchial fistula connect to the pharynx, near the tonsil area, via the "internal" branchial fistula.[5]

INCIDENCE

Branchial clefts and fistulae represent about 23% of cervical masses in children.[6] The "rule of 80" is often applied in adults, which states that 80% of nonthyroid neck masses in adults are neoplastic and that 80% of these masses are malignant. A neck mass in a child, on the other hand, has a 90% probability of being benign.

BRANCHIAL ANOMALIES

First-branchial-cleft anomalies account for less than 10% of all of the branchial cleft defects.[7] They have a wide range of presentations, manifesting in a sinus, fistula, or cyst anywhere between the floor of the external auditory meatus and the submandibular region (Figure 34.3).[8] Clinically, they can present with either a persistent purulent discharge from the ear, preauricular swelling in the parotid area, or fistula in the neck above the hyoid bone. However, they are most commonly associated with an infection, often being initially treated with a course of antibiotics or unnecessary repeated incision and drainage of an abscess.[7,9] The relationship of

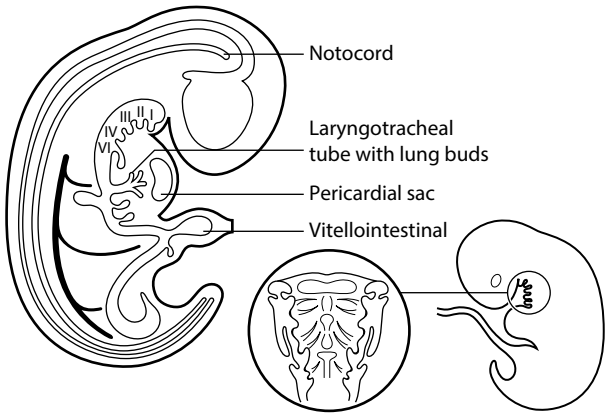

Figure 34.1 Schematic illustration of the embryo with the pharyngeal arches (I–VI).

Table 34.1 Summary of the derivatives of the pharyngeal arches

Arch	Muscles	Nerve	Cartilage, bone, and ligament
I	Muscles of mastication	Mandibular division of trigeminal nerve	Malleus, incus Sphenomandibular ligament
II	Muscles of face and scalp	Facial nerve	Stapes Styloid process Styloid ligament Lesser horn and upper part of body of hyoid bone
III	Stylopharyngeus	Glossopharyngeal nerve	Greater horn and lower part of body of hyoid bone
IV	Cricothyriod	Superior laryngeal branch of vagus nerve	Thyroid cartilage
VI	Intrinsic muscles of larynx	Recurrent laryngeal branch of vagus nerve	All laryngeal cartilages *except* thyroid cartilage

the facial nerve to the anomaly is variable, with careful and meticulous surgical dissection needed to avoid nerve paralysis.[10] In a series of 39 patients with first-branchial-cleft anomalies reported, 6 patients developed temporary facial nerve paralysis, and only 1 (2.5%) patient developed permanent damage.[11] Diagnosing first-cleft anomalies can be challenging, with the anomaly often closely related to the parotid gland. Examining the external auditory meatus may reveal a fistula, thus linking the parotid swelling or lateral neck mass to a first-cleft anomaly. Preoperative imaging with magnetic resonance imaging (MRI) allows assessment of the extent of the anomaly, especially in the parotid area, and high-resolution computed tomography (CT)

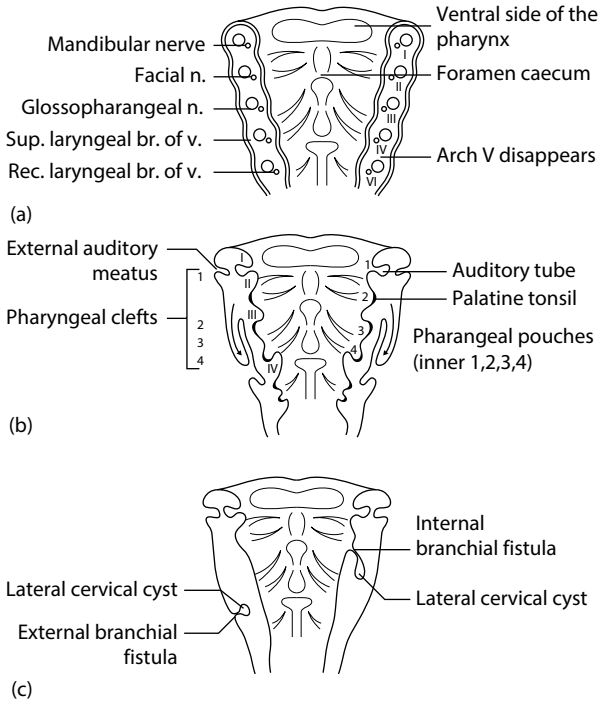

Figure 34.2 Illustration of the pharyngeal arches (I–VI) with their own nerve supply. **(a,b)** The mesoderm of the second pharyngeal arch grows downward, burying in the process the second, third, and fourth pharyngeal clefts. **(c)** Incomplete closure of these pharyngeal clefts leads to the formation of branchial anomalies such as a cyst or fistula.

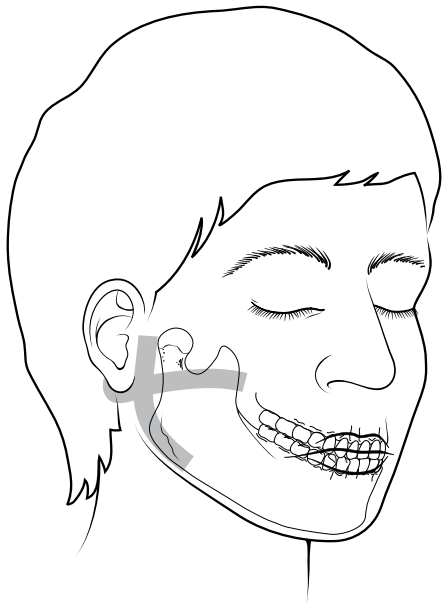

Figure 34.3 Shaded area on the face represents locations where the first-branchial-cleft anomalies would be generally located.

imaging shows its exact relationship to the external auditory canal and the middle ear.[11] Complete surgical excision is the treatment of choice, which often necessitates a superficial parotidectomy, with careful preservation of the facial nerve. Methylene blue injection into a draining tract prior to excision may facilitate removal. Recurrent infections or previous surgical interventions will increase the morbidity of the operation.[12] That is why it is essential to have an adequate preoperative workup prior to any surgical intervention.

Second-branchial-cleft anomalies are the most common (95%),[13] often presenting along the anterior border of the sternocleidomastoid muscle as a sinus, fistula or cyst, typically at the junction of the upper two-thirds and lower third of the muscle. The fistula typically travels deep to the platysma muscle along the carotid sheath between the external and internal carotid artery, above the hypoglossal and glossopharyngeal nerves, and ends near the tonsillar fossa (Figure 34.4).[8] Deep fistulas or sinuses would generally necessitate two or three "stepladder" or McFee incisions in order to completely remove the entire tract. However, the majority of the anomalies manifest as cysts[14] and rarely present as a full fistula tract.[13]

Bailey[15] described four types of cysts. Type 1 is superficial and lies beneath the platysma and cervical fascia, but anterior to sternocleidomastoid process. Type 2 cysts, which are the most common, characteristically lie on the great vessels and may be adherent to the internal jugular vein. Type 3 cysts course between internal and external carotid artery and extend to the lateral wall of the pharynx. Type 4 cysts lie against the pharyngeal wall.

Studies of less invasive procedures are promising, including sclerotherapy[16,17] and endoscopic excision.[18] However, complete surgical excision is the treatment of choice, with recurrence being the most common postoperative surgical complication. A large series of 208 cases showed recurrence in 21% of those with a history of prior surgical intervention, 14% with a history of infection, and 3% with a history of neither.[19]

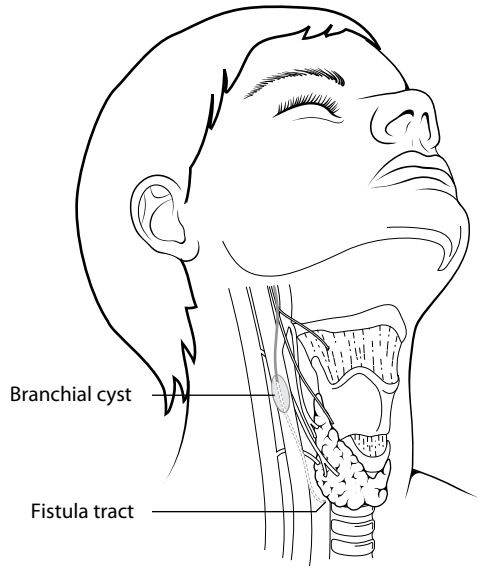

Figure 34.4 Second branchial cleft cyst and fistula tract coursing between the internal and external carotid arteries, above nerves IX and XII, ending near the tonsillar fossa.

Third- and fourth-branchial-cleft anomalies are rare, accounting for 2%–8% and 1%–2% of all branchial anomalies, respectively.[7,20] Clinically and radiologically, it can be difficult to distinguish between the two, as both types begin at the pyriform sinus and end blindly in the paratracheal or thyroid region. Ninety-seven percent of the lesions occur on the left side.[19] Although rare anomalies, they can have devastating respiratory consequences, presenting with acute stridor.[21,22] or acute thyroiditis.[23,24] Diagnosis can be quite challenging, as these cysts are generally subjected to repeated incision and drainage, being mistaken for a simple abscess. A plain film showing air or fluid levels within the cyst can help differentiate a branchial anomaly from other causes of pediatric neck masses. The pharyngeal opening may be visualized by flexible fiber-optic nasopharyngoscopy or demonstrated using a barium meal.[25] In a series of 43 patients with acute suppurative thyroiditis, nearly 88% of the patients were documented to have a pyriform sinus fistula.[24] Therefore, it should be a consideration for any patient presenting with acute thyroiditis to have a potential third- or fourth-branchial anomaly as an underlying cause, and to promote a search for it. The only definitive way of distinguishing an anomaly as being a third or fourth arch is through surgical dissection, which is the treatment of choice, ensuring that the tract is completely excised to avoid risk of recurrence. This is done by demonstrating the relationship of the tract to the recurrent and superior laryngeal nerves. A tract that goes inferior to the superior laryngeal nerve (fourth arch) and superior to the recurrent nerve (sixth arch) is derived from the fourth pouch. However, if the tract passes superior to the superior laryngeal nerve (fourth arch), then a third-pouch origin is likely. Vocal cord paralysis is a potential complication as a result of the dissection.

CT scan and MRI are the imaging modalities of choice to assess the extent and depth of any branchial cleft cysts.[26]

Endoscopic-assisted branchial cleft excision has been recently advocated by several recent case reports and case series to improve cosmetic results,[27] with almost identical recurrence rates particularly for third and fourth branchial anomalies.[28,29] Surgical approaches include the axilloareolar, retroauricular, posterior occipital, and transcervical approach. Teng et al.[27] reported a series of 24 patients undergoing branchial cleft excision, 8 of whom underwent a transcervical endoscopic approach using gasless 4 mm endoscopic technique through an average 2.1 ± 0.2 cm skin incision versus the standard open approach via 4.1 ± 1.5 cm incision. Two out of the eight patients encountered transient weakness of the greater auricular nerve and marginal mandibular nerve.[27]

THYROGLOSSAL DUCT CYSTS AND SINUSES

Thyroglossal duct anomalies are the most common congenital anomalies of the neck, constituting nearly 70% of all cervical neck masses in children.[30] They represent remnants from the embryological migration of thyroid tissue from the foramen cecum to the thyroid fossa. Clinically, they usually present as a palpable, nontender midline neck mass that elevates with swallowing or protrusion of the tongue (Figure 34.5). It is important to note that 10%–24% of these cysts are located laterally, often to the left.[31]

Ultrasonography is the imaging technique of choice for these lesions, especially to document the presence of a normal thyroid and to rule out thyroid ectopia.[32] The reported incidence of an ectopic thyroid being misdiagnosed as a thyroglossal cyst is 1%–2%.[33]

The Sistrunk procedure, with dissection of the tract up to the hyoid bone, including its midportion, is accepted as the main operation of choice with the lowest recurrence rate of around 3%.[32,34] Malignancy of the thyroglossal duct cysts is rare (1%),[33,35] with the majority (80%) of histological examination revealing a papillary adenocarcinoma.[36,37]

CONGENITAL MIDLINE CERVICAL CLEFTS

Congenital midline cervical clefts (CMCCs) are rare developmental anomalies, with variable severity from patient to patient and with variable length and width.[38] The embryological origins have not been fully elucidated, but they are thought to be a result of failed mesodermal fusion of the first or second branchial arches in the midline.[39] There has been no observed familial inheritance pattern. Affected patients present soon after birth, with common characteristic features including midline fissure or atrophic skin, a caudal-directed sinus that may have mucoid discharge, subcutaneous fibrous cord, and a thickened nipple-like projection at the superior aspect of the lesion.[40] There is often a subcutaneous fibrous cord of variable length spanning anywhere along the midline of the neck from the symphysis of the mandible to the suprasternal notch. It is occasionally seen in conjunction with thyroglossal and bronchogenic cysts. CMCC presenting with a midline cervical sinus can be differentiated from a sinus associated with a thyroglossal cyst based on the orientation of the sinus. The sinus in CMCC is generally caudally directed, whereas with thyroglossal duct cysts, the associated sinus will tend to be directed cranially. The distinction between these two clinical entities is important since the surgical approach is vastly different. Thyroglossal duct cyst excision involves removal of the central portion of the hyoid bone (Sistrunk operation), whereas CMCC does not involve the hyoid bone.[40]

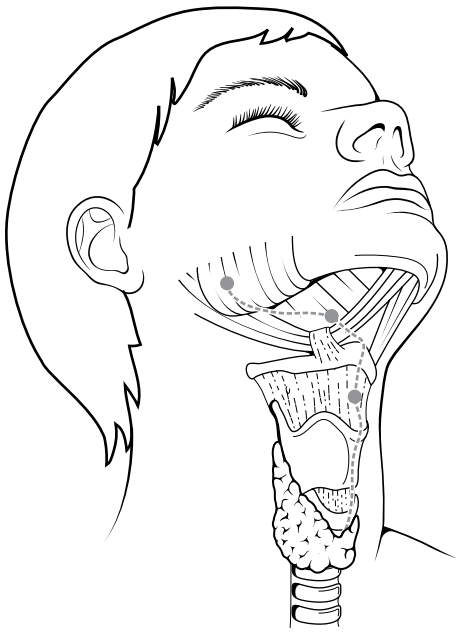

Figure 34.5 Illustration for the thyroglossal duct tract.

Diagnosis of CMCC is mainly clinical, but imaging studies such as ultrasound may be obtained to evaluate the thyroid gland and hyoid bone to rule out any associated anomalies. CT or MRI can be done for a more thorough assessment of involvement of any deeper neck structures.

Midline cervical clefts need to be completely excised because if left untreated, the cleft will cause cicatrical skin contracture, limiting neck extension and causing webbing of the neck. It is recommended to excise the cleft between 10 and 12 weeks of age, before tethering of the anterior skin occurs.[41] Simple linear closure has been reported to result in hypertrophic scarring and recurrent neck contracture.[42] As a result, a step Z-plasty lengthening procedure is the preferred surgical management of this congenital anomaly, as it provides a superior cosmetic result compared to linear closure and adds the lengthening effect on the anterior neck skin that aids in preventing recurrent contracture.[40] Depending upon the angle of the Z-plasty chosen, a 30°, 45°, or 60° angle will result in 25%, 50%, and 75% gain of length, respectively. Any smaller angle results in risk of necrosis of the tip of the flap, and any broader angle will make flap rotation difficult (Figure 34.6).[40]

DERMOID CYSTS

Cervical dermoid cysts are benign tumors that are frequently mistaken for a thyroglossal duct cyst due to similar presentation and location. They are of ectodermal and mesodermal origin, and a definitive diagnosis is usually made during histologic examination revealing hair follicles, smooth muscle, sebaceous glands and connective tissue elements.[43] They are thought to arise due to trapping of epithelial rests during midline fusion of the first and second branchial arches.[44] Surgical excision is the treatment of choice.

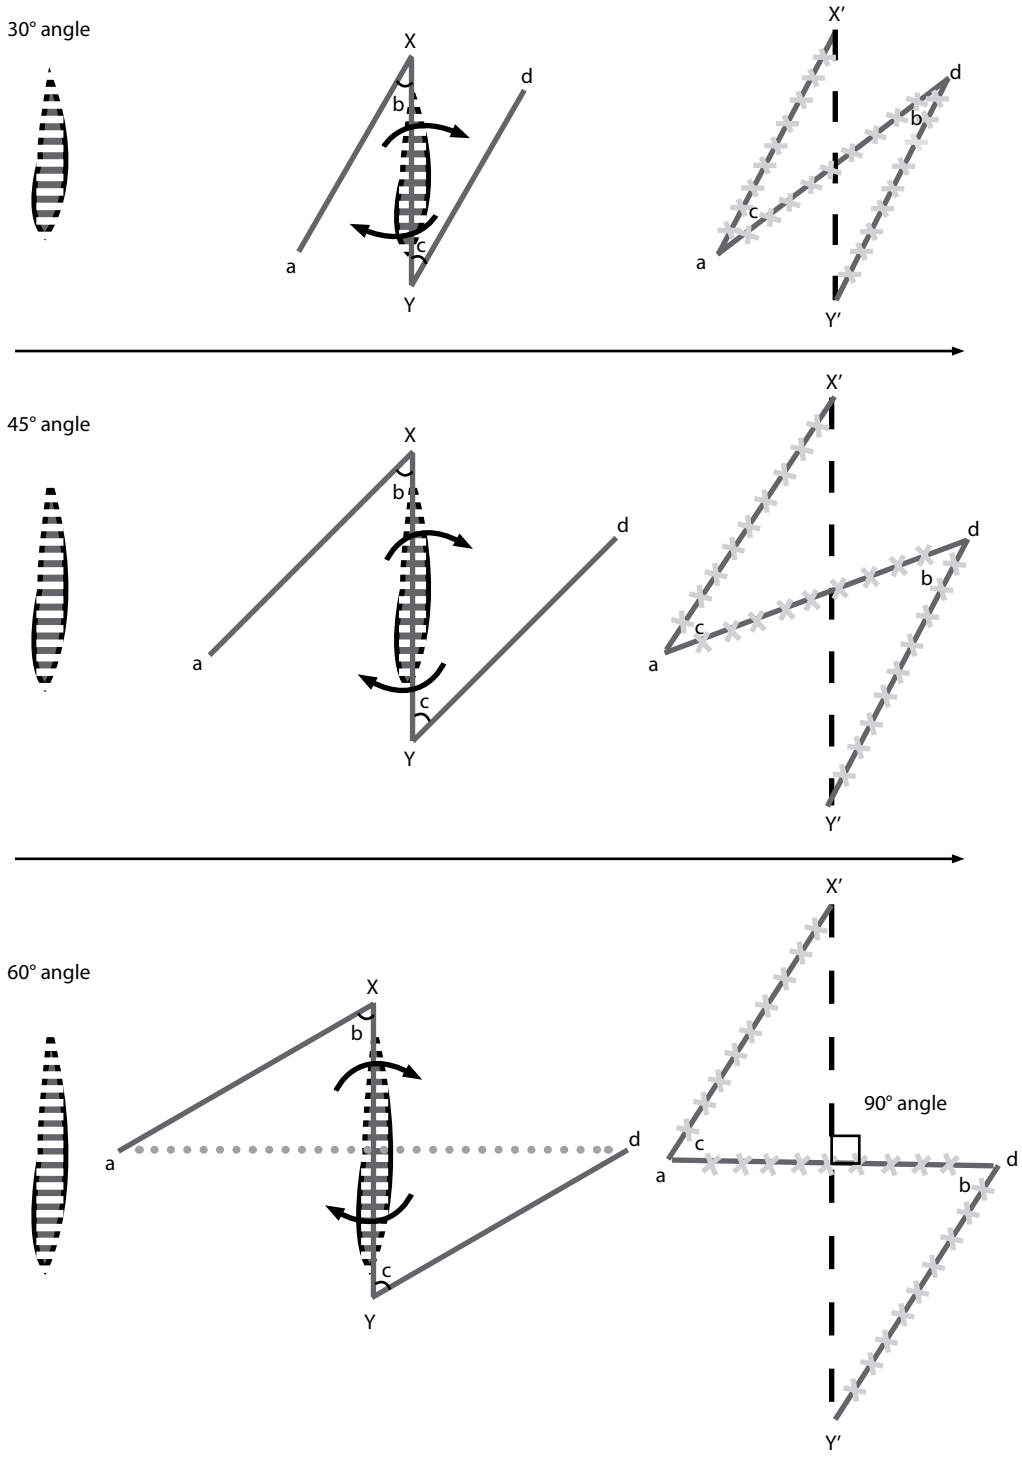

Figure 34.6 Z-plasty technique involves creating two opposing triangular transposition flaps that are rotated synchronously to close central defect. Lateral limbs are equal in length to central limb tissue defect. Angles vary from 30° to 60° depending on desired length gain. Z-plasties may be single, especially for lesions that are equal to 2 cm or less, or arranged in series with multiple flaps to allow shortening of the lateral limbs so as to avoid anesthetic boundaries. Central defect (X–Y) with flap reference points (a–d) resulting in lengthening of wound (X′–Y′).

PREAURICULAR SINUSES AND CYSTS

Preauricular sinuses are congenital malformations, usually noted during physical examination as small pits adjacent to the external ear, usually at the anterior margin of the ascending limb of the helix.[45] The incidence varies between different races, with the reported incidence ranging between 0.02% and 5%, with higher incidence amongst African American and Asian populations.[46–49] They are mostly unilateral with usually an asymptomatic presentation; however, they can present with purulent discharge from the sinus opening, resulting in facial cellulitis or abscess formation, which is the most common indication for a fistulectomy. Surgery should be performed once the infection has resolved, whenever possible, with the recurrence rate after surgery being reported between 3.7% and 36%, with the rate much higher if infection preceded surgery.[49–51] In the process of excising the sinus tract, various techniques can be used to identify its extension, but it is recommended to combine the use of dye injection with probing using a fine lacrimal duct probe at the time of surgery.[47,49] Use of microscope guidance for sinus excision has been reported to have a lower recurrence (0.9%) compared to the standard methylene blue dye and probe guidance (4.3%).[52]

RANULA

Ranulas are divided into simple and plunging ranulas. Simple ranulas are either mucus retention cysts that are restricted to the oral cavity floor or else mucus extravasation pseudocysts. Plunging ranulas are mucus extravasation pseudocysts that originate from the sublingual glands and herniate through the mylohyoid muscle to present as a cervical neck swelling, which may be confused with a submandibular mass when there is no intraoral component.[53] The ideal management for both of these lesions remains controversial, ranging from injecting sclerosing agents to different surgical techniques. Although most would agree to surgically excise them, a consensus on the ideal technique and approach is lacking.

Injecting simple and plunging ranulas with OK-432 (a mixture of a low-virulence strain of *Streptococcus pyogenes* incubated with benzylpenicillin) has a reported success rate of 74% and 100%, respectively, but only after multiple injections.[54,55] Most advocate marsupialization of the oral ranula, as illustrated in Figure 34.7, which is associated with a recurrence rate of around 20%.[56] Others advocate surgical excision of the cyst alone, which has a recurrence rate of 12%.[56] Some authors prefer to remove the sublingual gland, seen as the definitive treatment with the lowest recurrence rate, along with the cyst. This, however, is associated with a low incidence of lingual nerve and submandibular duct damage due to the more invasive intervention. Others simply excise the sublingual gland transorally along with evacuation of the ranula, which is seen as the modality yielding the lowest recurrence (1%–2%) and lowest complication rates for both oral and plunging ranulas.[56,57] A transoral approach for plunging ranulas is associated with a lower morbidity and complication rate compared to the cervical approach, as the latter places the marginal mandibular and hypoglossal nerves at risk of damage.[58,59] Removing the origin of the disease, usually the sublingual gland, is the key to successful treatment of simple and plunging ranulas.

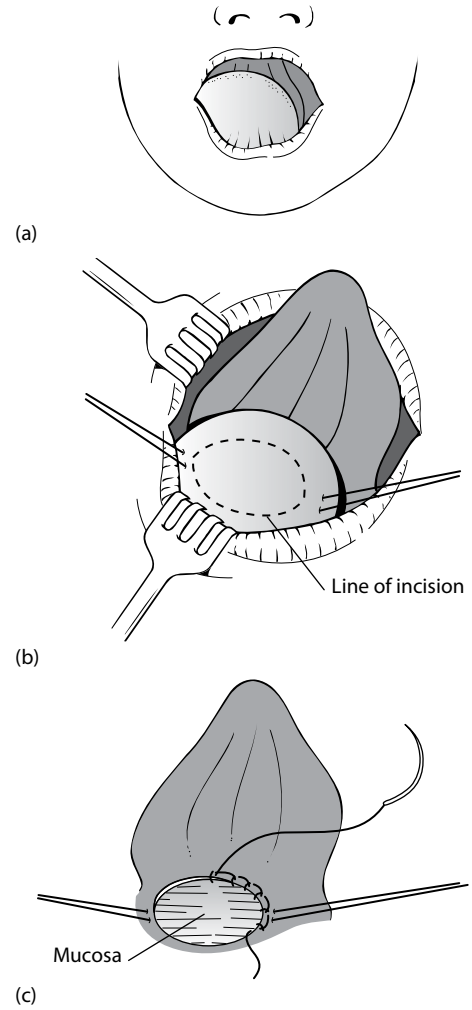

Figure 34.7 **(a)** Large ranula occupying the floor of the mouth. **(b)** Line of incision. **(c)** Continuous 4-0 Vicryl stitch to complete marsupialization.

CYSTIC HYGROMA (CYSTIC LYMPHANGIOMA)

Cystic hygromas or lymphangiomas are nonmalignant cystic (unilocular or multilocular) abnormalities of the lymphatic system, mostly occurring in the cervicofacial region with a predilection to the left side, and with a prevalence of 1 in every 6000 live births.[60] They can occur in the axilla, mediastinum, retroperitoneum, and rarely in the extremities with variable sizes, ranging from a few centimeters in diameter to large masses, potentially filling a large portion of the thorax.[61,62]

The term *hygroma* is derived from Greek, meaning moist or watery tumor. Hygromas have equal sex distribution. They

rarely self-resorb after aspiration of the cystic fluid, which is usually clear or amber-colored, and occasionally hemorrhagic,[62] usually resulting in rapid reaccumulation. They can present as a congenital birth defect or be acquired at a later stage in life, with the majority (80%–90%) presenting by 2 years of age.[63,64]

They are thought to arise due to the failure of lymph vessels to communicate with the venous system, with abnormal budding and/or sequestrations of primitive embryonic lymphatic tissue.[65] Lymphangiomas are often classified into three types based on histology: capillary lymphangioma or lymphangioma simplex, composed of small thin-walled lymphatics; cavernous lymphangioma, consisting of larger lymphatic channels with adventitial coats; and cystic lymphangioma (hygroma), made up of larger macroscopic lymphatic spaces.[66,67] Immunocytochemical staining for CD31 (platelet endothelial cell adhesion molecule-1), a stain that is intended to reveal the endothelium of small vessels, confirms the diagnosis.

Diagnosis can be made with a good history and clinical examination, due to the characteristic clinical appearance, usually soft, compressible, and transilluminates with light. In a series of 168 patients with lymphangiomas, 41% were diagnosed based on clinical examination alone. Ultrasonography is a useful aid in diagnosis, revealing a cystic structure rather than solid. However, CT or MRI can show the full extent of the lesion and its relationship with the surrounding structures.[63,68] The radiologic characteristics of cystic hygroma are consistent with a fluid-filled, multiseptate mass with enhancing septal walls.[61]

Malignant transformation has not been reported; however, complete surgical excision is the surgical treatment of choice. It is generally recommended to remove the mass due to its potential for growth, which can compromise the airway if in the cervicofacial area, as well as disfigurement and recurrent bouts of inflammation, which unfortunately does not induce regression.[69] Aspirating the lesion may be useful for emergency decompression. Complete surgical resection can be difficult in the infiltrative form. Hygromas can be complicated with recurrences after surgical excision, reported to be 12% in patients who have undergone complete excision for neck lesions,[63] as well as with lymphangitis and cellulitis, which can lead to sepsis, prompting the need for intravenous antibiotics. It is advised that the initial approach for patients with recurrences after complete excision is to observe and wait, as spontaneous regression has been reported in up to 12% of patients after surgery. Other alternative treatments include intralesional injection with bleomycin or OK-432, with a reported response rate of 55%–60%,[70,71] and argon beam ablation and laser treatment. These modalities may be useful in patients with complex diffuse lesions when surgical therapy may be difficult to achieve a complete cure, or when vital structures are involved with the lesion.[72–74]

TORTICOLLIS

Torticollis or "sternocleidomastoid tumor" results from shortening of the sternocleidomastoid muscle, which may lead to limitation of neck movement and craniofacial deformity. The term *torticollis* is derived from two Latin roots, *tortus*, meaning twisted, and *collum*, which means neck.[75] It is considered one of the most common congenital musculoskeletal anomalies after developmental dysplasia of the hip and clubfoot, with an incidence of 0.3%–2%.[75–77] Although various theories have been proposed with regard to its etiology, such as birth trauma, intrauterine malposition, infectious myositis, and compartment syndrome, an exact cause has not been identified.[75] Diagnosis is usually established on clinical examination of a firm, spindle-shaped mass within the sternocleidomastoid muscle. Ultrasonography is the imaging modality of choice to confirm the diagnosis, usually hypoechoic compared to muscle.[78] This unilateral contraction of the muscle results in the head tilting toward the affected side and the face rotating to the opposite side, as is seen in Figure 34.8. This therefore can induce plagiocephaly and facial asymmetry at presentation. Treatment includes physical therapy, which is the primary treatment modality, with over 95% achieving passive cervical rotation after physiotherapy.[79] Physiotherapy involves stretching the affected muscle to an overcorrected position by gentle, even, and persistent motion with the infant lying in a supine position. The head is flexed forward and away form the affected side, and the chin is rotated toward the affected side. Some use botulinum toxin injection as an adjunct to physical therapy in those who have not responded to 3 months of conservative management.[80] Failure to respond to conservative treatment after the age of 1 year may necessitate the need for surgical intervention. Surgical options include

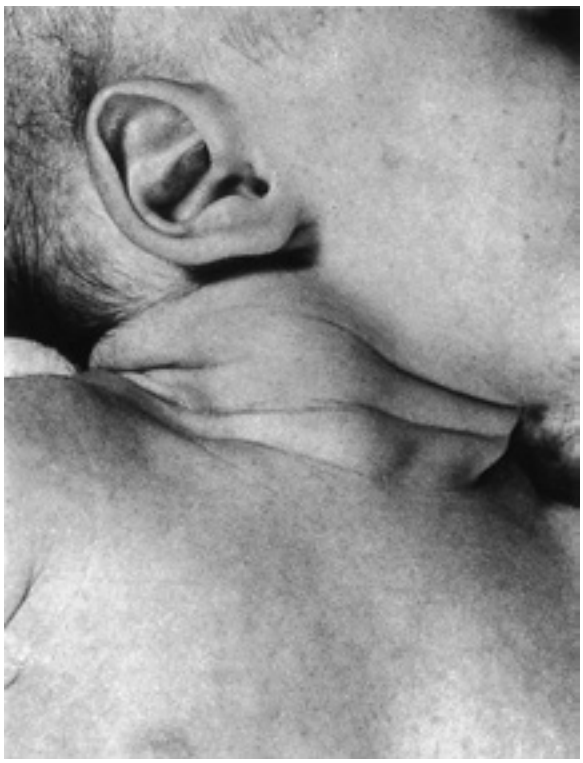

Figure 34.8 Right sternomastoid tumor in a 3-week-old infant.

unipolar or bipolar release, release with Z-plasty, transaxillary endoscopic release, and muscle resection. The transaxillary subcutaneous endoscopic approach has recently been developed to avoid the potential for poor cosmesis from neck scars.[81] The overall outcome from all these treatment modalities is excellent.

Stridor in infants

SAM J. DANIEL AND FAISAL ZAWAWI

INTRODUCTION

Stridor refers to the abnormal noisy breathing that occurs due to turbulent airflow passing through the narrow lumen of a partially obstructed airway. The degree of stridor is dictated by the amount of reduction in lumen size, whereas the type of stridor is determined by the location of the obstruction.

Stridor can be classified as inspiratory, expiratory, or biphasic. Inspiratory stridor is classically caused by a supraglottic obstruction (above the level of the vocal cords), and expiratory stridor is caused by tracheal and bronchial obstruction. At these levels, often, the issue is a dynamic obstruction. This is the reason behind single-phase stridor. At the level of the vocal folds and subglottis, there is usually a fixed obstruction. This explains why at these locations, a biphasic stridor occurs.

There are many causes for stridor in a newborn. These can be classified either by location (supraglottic, glottic, subglottic, and tracheal) or by the type of disorder causing the airway obstruction (congenital, infectious, neoplastic, etc.) (Table 35.1).

In this chapter, we will review the most common and important differential diagnoses.

SUPRAGLOTTIC DISORDERS

Laryngomalacia

This is the most common cause of stridor in neonates. It is usually caused by an immature neuromuscular tone and/or weak and immature cartilages of the larynx. This leads to a dynamic obstruction with inspiration. Classically, laryngomalacia does not become symptomatic until 6–8 weeks after birth.[1,2] This is because at birth, the inspiratory pressures are not enough to collapse the supraglottic immature structures. As the child grows, the lungs mature and become able to generate enough pressure that can overcome the supraglottic cartilage strength.[3]

There are numerous classifications for laryngomalacia based on either anatomy or severity. The features of laryngomalacia by anatomic designation are collapse of the cuneiform and corniculate cartilages, posterior inspiratory displacement of the epiglottis, short aryepiglottic folds (AE folds), and long tubular (omega-shaped) epiglottis.[3–10] In severe cases, the vocal cords cannot be visualized.

Laryngomalacia usually presents with stridor that worsens in the supine position, with crying, and with feeding. Findings that should prompt a more urgent evaluation by an airway specialist (red flags) include apnea, tachypnea, cyanosis, feeding difficulties despite adequate acid suppression and food texture modification, failure to thrive, weight loss, evidence of aspiration or pneumonia, and cor pulmonale. Gastroesophageal reflux disease (GERD) is associated with laryngomalacia.[11] In fact, symptoms of GERD should be carefully sought while taking history to assess the severity of the reflux and the need for treatment. These symptoms include back arching after feeds, spit-ups, and recurrent emesis.

A complete physical examination including a flexible laryngoscopy on an awake child is performed routinely to confirm the diagnosis. Findings on physical examination tend to vary according to the severity of the condition. Red flags listed previously as well as suprasternal tug or retraction are suggestive of a more severe obstruction. During the endoscopy, features of laryngomalacia should be documented alongside signs of reflux.[12]

Laryngomalacia usually resolves spontaneously by the age of 12–18 months. In mild to moderate cases, medical therapy with aggressive GERD treatment is usually all that is needed to control the patients' symptoms. However, severe laryngomalacia resulting in failure to thrive, apneas, cyanotic spells, and/or cor pulmonale is likely to require surgical treatment.

Supraglottoplasty is the surgery of choice. It addresses the various contributing factors of the supraglottic collapse or obstruction. Usually, all that is needed is an AE fold release, although occasionally, addressing the redundant cuneiform

Table 35.1 Etiologies of airway obstruction in the newborn

Congenital	Laryngomalacia, subglottic stenosis, laryngeal cysts, laryngeal stenosis/web, local fold immobility, subglottic cysts, tracheal stenosis, complete tracheal rings, tracheomalacia, vascular anomalies, thymic masses
Infections	Epiglottitis (rare), angioedema, laryngotracheobronchitis, bacterial tracheitis
Neoplasm	Vascular tumors, recurrent respiratory papillomas, thyroid and mediastinal tumors
Other	Acquired vocal fold immobility (scar), foreign body, post-intubation trauma

or corniculate cartilages, the arytenoid mucosa, and a long epiglottis are necessary.[13] In some cases, an epiglottopexy is required, to lift the epiglottis forward and attach it to the base of tongue or hyoid bone. Also in very rare occasions, a tracheostomy is needed.

It is important after a supraglottoplasty to monitor the child's breathing and feeding. Opening up the airway may increase the risk of airway penetration or aspiration.[6,13]

Laryngeal cysts

Congenital laryngeal cysts are rare findings in an infant. When they occur, the infant usually presents with upper airway obstructive symptoms. They can be extralaryngeal (vallecular cysts) or endolaryngeal (saccular cysts).[14]

Vallecular cysts are unilocular cysts that arise from the lingual surface of the epiglottis. The pathogenesis of their development is thought to be due to mucus gland obstruction or developmental malformation during the gestational period. Infants with vallecular cysts present with symptoms of supraglottic airway obstruction that are similar to laryngomalacia. Flexible laryngoscopy is usually able to diagnose these cysts. Therefore, a focused laryngoscopy examination is encouraged while assessing infants with laryngomalacia-like picture. In almost all cases, these infants are treated surgically using an endoscopic approach. Complete excision of the cyst is often feasible, especially in older children, but when not feasible, marsupialization of the cyst is performed.

Congenital saccular cysts are rare anomalies that are believed to form due to failure of maintaining a saccular orifice. They develop into an abnormal herniation of the saccule but without an opening at the ventricle. These cysts are filled with mucus.[14]

There are two types of saccular cysts, anterior and lateral saccular cysts. Anterior cysts enlarge medially and posteriorly between the true and false cords, protruding into the lumen of the larynx. Lateral cysts progress in a posterosuperior direction, causing distension of the false vocal cord and AE fold. The growth of such cysts is restricted by the thyroid cartilage, but lateral extension through the thyrohyoid membrane may occur, resulting in a neck mass. Saccular cysts can also be divided into endolaryngeal (type 1) and extralaryngeal (type 2). The second type is further classified into endodermal elements only (2a) and endodermal and mesodermal elements (2b).[15]

Saccular cysts present with inspiratory stridor and respiratory distress at birth. Weak or muffled cry and dysphagia can also occur. A flexible fiber-optic laryngoscopy allows the visualization of fullness at the level of the ventricle, and in larger cysts, a round swelling protruding into the laryngeal lumen. Imaging is recommended to determine the extent of the cyst and plan the intervention after securing the airway.[14–18]

Endolaryngeal cysts are usually excised endoscopically. Extralaryngeal cysts often require an open approach that involves either dissecting through the thyrohyoid membrane or creating a thyroid ala window to approach the ventricle. Preoperative careful assessment with cross-sectional studies can help reduce the risk of recurrence.[14–18]

GLOTTIC AND SUBGLOTTIC DISORDERS

Vocal fold immobility

There are several causes for vocal fold immobility. These include traumatic causes such as injury during thoracic and cardiac surgery, trauma during delivery that could result in nerve stretch injury, or trauma from endotracheal intubation. Other important causes are neurologic such as hydrocephalus and Arnold–Chiari malformation.[19–22]

There are two different presentations of vocal fold immobility. In unilateral vocal fold immobility, the children often present with episodes of choking with feeds, aspiration, and weak voice and cry. Stridor in these patients could be due to a coexistent disorder, e.g., laryngomalacia. On the other hand, infants with bilateral vocal fold immobility can present with stridor that could be either uniphasic (inspiratory only) or biphasic, and tend to have a strong cry.[19–22]

Physical examination is the key to diagnose these conditions, with awake flexible laryngoscopy being the gold standard. Despite that, findings can be challenging to interpret. This is due to the movement that is caused by the Bernoulli effect of air passing through the vocal folds. Other causes of difficult examination include laryngomalacia covering the view of the cords and supraglottic hyperfunction.

Once vocal fold immobility is diagnosed, cross-sectional imaging of the head down to the chest should be performed looking at the whole course of the recurrent laryngeal nerve. The child should be assessed for swallowing function. Also in bilateral immobility, it is imperative to assess the patient's ability to ventilate well. Overnight oximetry and polysomnography may be warranted depending on the severity of the case.

Laryngeal electromyogram (LEMG), although challenging to perform in neonates, can provide useful information

to differentiate paralysis from ankyloses or cord fixation. This could guide the therapeutic intervention needed.[23]

Some causes of immobility are fully reversible. For an example, when a Chiari malformation is decompressed, vocal cold mobility tends to return to normal. If the cause cannot be determined, as in idiopathic cases, the patient should be carefully observed, as most cases recover in the first 2–3 years of life. There are reports for even further delays in recovery in some children with vocal fold paralysis which makes identifying a precise time of potential recovery challenging.[19–21,24–26]

If the patient is unable to ventilate appropriately, a tracheostomy is usually necessary.[24] Recently, new studies have looked at the use of botulinum toxin injection into the laryngeal muscles in order to gain a few millimeters that could prevent the need for a tracheostomy.[27]

There are also several procedures that can be performed to help open up the glottic airway in children with bilateral vocal fold immobility. Most of these procedures are irreversible; hence, they should not be performed early on in life until the immobility has been persistent for few years and the chances of spontaneous recovery are deemed negligible. Vocal fold lateralization, posterior cordotomy, arytenoidectomy, posterior cricoid graft, and anterior and posterior cricoid splits with balloon dilatation are a few of many procedures that can be performed to help a child with bilateral vocal fold immobility.[19,21,22,27–35]

Glottic stenosis

Glottic stenosis is defined as a narrowing of the lumen at the level of the vocal folds. The narrowing can be due to fibrosis, scarring, or webbing. The cause of the stenosis (whether anterior or posterior) is either congenital or acquired, with the latter being much more common. Acquired conditions can be posttraumatic, infectious, inflammatory, or iatrogenic in origin. The risk of developing a posterior glottis stenosis is about 15% in patients who have been intubated for more than 10 days. Factors that increase the risk even further are traumatic intubation, multiple extubations and reintubations, oversized endotracheal tube, GERD, and infections.[36]

Congenital laryngeal web is due to failure of complete recanalization of the larynx during embryogenesis. This accounts for 5% of all laryngeal anomalies, with 75% of those webs occurring at the level of the vocal folds.[37] Patients who are diagnosed to have anterior glottic web should be worked up genetically to rule out other syndromes, most importantly velocardiofacial syndrome.[38]

Glottic webs typically present with airway obstructive symptoms, biphasic stridor, weak voice, and occasionally aphonia. Most of the congenital glottic webs are located anteriorly.

Flexible laryngoscopy is able to identify most of the anterior glottic webs. These patients should undergo a rigid bronchoscopy for further assessment of the airway especially to identify the thickness of the web and to rule out other airway anomalies. Cohen's classification can be useful to classify glottic webs according to their severity. Grade 1 consists of a thin anterior web involving less than 35% of the glottis with no subglottic extension. In grade 2, there is up to 50% glottic stenosis with some subglottic extension. In grade 3, up to 75% of the glottis is involved with subglottic extension (potentially cartilaginous), and in grade 4, there is more than 75% glottic stenosis with thick subglottic cartilaginous involvement.

Infants with glottic stenosis are managed according to the severity of their airway blockage. Infants with grades 1 and 2 are usually observed until 3 years of age prior to surgical intervention.[36,37,39] Infants with grades 3 and 4 usually have breathing difficulties requiring a more urgent airway intervention.[37] This may include a temporary tracheostomy.

There are several surgical options to repair a web. The choice is based on the infant's clinical picture, the degree of stenosis, as well as the surgeon's preference. Open approaches involve performing a complete laryngofissure, cutting the web, and placing a keel. Endoscopic approaches can also be used, severing the web with various types of mucosal flaps to reduce the risk of restenosis. Dedo and Lichtenberger described a procedure in which the web is severed and a keel is placed endoscopically, using a specialized endo-extralaryngeal needle carrier.[37,39–42]

The most common complication is restenosis, and for that reason, these infants are followed closely to detect symptoms and signs of restenosis.[40]

Subglottic stenosis

The subglottis extends from the under surface of the vocal folds to the inferior edge of the cricoid cartilage. It is the narrowest area of an infant airway, measuring normally 4.5–7 mm in a full-term newborn. A preterm newborn's subglottis measures approximately 3–4 mm in diameter. Narrowing of the subglottis, i.e., subglottic stenosis, can be congenital or acquired, the latter being more common. This is due to the improved neonatal intensive care units with improved survival of premature infants, who would require prolonged ventilation and intubation due to premature lung disease. Most of the acquired form is secondary to prolonged intubation, laryngeal trauma, or iatrogenic subglottic damage from an airway procedure. Risk factors for developing subglottic stenosis include recurrent intubation, use of a large endotracheal tube, tracheitis, and infection while the patient is intubated.

Congenital subglottic stenosis is a diagnosis of exclusion. The hypothesis behind its development is failure of recanalization of the tracheal lumen.[43] It can be classified into two types: The first is a cartilaginous type where the abnormality is in the cricoid cartilage, i.e., an elliptical cricoid that causes the subglottic lumen to be narrower than it should be. The other type is membranous, in which there is a thin soft tissue narrowing the lumen.[44,45]

Children with subglottic stenosis present with biphasic stridor and respiratory distress. Another presentation is failure of extubation due to increased work of breathing and stridor in an otherwise fit patient to be extubated. Milder forms of subglottic stenosis can present with a barking cough and early onset of recurrent croup.[46]

While assessing these patients, a thorough history should be obtained with a focus on prematurity, comorbidities, and a prior history of intubation, in addition to choking spells, feeding issues, reflux, and failure to thrive.[46]

General examination of the infant will give the physician a hint as to the level of the obstruction. Biphasic stridor is a classic finding in patients with subglottic stenosis. Increased work of breathing or shallow breathing indicates that the patient is tiring out and about to decompensate.[46]

In patients with only subglottic stenosis, flexible laryngoscopy will show normal anatomy, though on some occasions and in more severe cases, a subglottic narrowing can be visualized. If subglottic stenosis is not diagnosed on a flexible laryngoscopy, it is not recommended to pass the scope through the vocal cord, as this may result in life-threatening airway obstruction due to laryngospasm.[46]

The gold standard diagnostic and evaluation tool is a rigid bronchoscopy performed in the operating room. This also allows the identification of secondary airway lesions and deformities if present. To complete the assessment, airway sizing should also be performed. This can be done using serial endotracheal tubes according to the Myer–Cotton staging system. In this method, a size-appropriate endotracheal tube is chosen according to age. After intubation and confirmation of the position, an air leak is tested. The endotracheal tube that will pass through the lumen, if one exists, and tolerate normal leak pressures (10–25 cm H_2O) can be compared to the expected age-appropriate endotracheal tube size. If the leak is found at less than 10 cm H_2O, then the tube is considered too small, and the procedure is repeated with the next size up. When the leak is found to be absent or present only at higher than 25 cm H_2O, the tube is deemed to be too big, and the test is repeated with a smaller tube. An appropriate tube to lumen should have an air leak between 10 and 25 cm H_2O. That size is then compared to the Myer–Cotton scale to determine the narrowing of the lumen. Based on that grading system, a grade 1 has less than 50% obstruction of the lumen, grade 2 is 51–70%, grade 3 is 71–99% obstruction, and grade 4 is when there is no lumen to be detected (complete obstruction).[47] Cross-sectional imaging, i.e., computed tomography (CT) and magnetic resonance imaging (MRI), are rarely necessary in these cases but may be of help to quantify the length of the narrowed segment, especially in cases with grade 3 or 4 subglottic stenosis.

The management of infants with subglottic stenosis is dictated by the presentation, symptoms, and severity of the stenosis. In milder forms, observation and GERD control can be sufficient.

In patients who failed extubation due to subglottic stenosis, management options include an anterior cricoid split.

Table 35.2 Candidacy criteria for anterior cricoid split in neonates

2 or more failed extubations due to a laryngeal cause
Weight > 1500 g
No ventilation requirement for >10 days
FiO_2 < 30%
No congestive heart failure for >1 month
No acute respiratory illness
No antihypertensive medications for >10 days

For infants to be candidates, they have to meet certain criteria to improve the outcome and the benefit of the procedure (Table 35.2). The procedure involves splitting the cricoid cartilage anteriorly and placing a larger endotracheal tube to stent the airway. On some occasions, a thyroid alar cartilage graft is used if the gap after the cricoid split is more than 3 mm. The patient is then extubated 5–7 days later.[48]

The surgical approach is determined based on the level and length of the segment, the involvement of the vocal folds, the mobility of the vocal folds, the swallowing assessment, and other comorbidities. Surgical options could be either endoscopic or open. Endoscopic approaches (e.g., balloon dilation and laser) are usually reserved for grades 1 and 2 stenosis, where as grades 3 and 4 would require an open approach.[49] Options include laryngotracheoplasty with rib grafts (anterior, posterior, or both) or cricotracheal resection and anastomosis.[44,46,50]

TRACHEAL DISORDERS

Tracheal anomalies, whether congenital or acquired, can be classified into three categories based on the patient's clinical presentation, endoscopic findings, and histological results. These categories are intrinsic tracheal anomalies, extrinsic tracheal anomalies, and acquired tracheal anomalies.[51]

Intrinsic tracheal anomalies are disorders involving the maturity of the tracheal cartilages, narrowed lumen due to complete tracheal rings, atresia, or webs. Extrinsic anomalies include vascular rings and aberrant innominate arteries. Acquired tracheal disorders occur with chronic tracheal infections, prolonged intubation, or inflammatory conditions like relapsing polychondritis.[52,53]

Tracheomalacia

Tracheomalacia is characterized by weakness of the tracheal cartilages, widening of the posterior wall, and reduced airway caliber. These result in tracheal collapse, which becomes more evident during increased airflow periods such as crying, feeding, or coughing.[51,53,54] Tracheomalacia can be associated with various airway defects (e.g., tracheoesophageal fistula and laryngeal clefts), cardiovascular defects, developmental delay, and GERD.[51,53,54]

Patients present with expiratory stridor (occasionally they could have biphasic stridor) that could resemble wheezing. During heavy breathing, the posterior wall advances

anteriorly, and on some occasions, it even touches the anterior wall, causing narrowing in the airway lumen. Initially, the symptoms start to get worse as the infant grows due to the increased respiratory movement.

Primary tracheomalacia is a rare disorder of the tracheal rings, whereas, more commonly, secondary tracheomalacia is when cartilage weakness results from a persistent external pressure. Frequent causes of secondary tracheomalacia include vascular compression, such as from a double aortic arche or innominate artery compression, and in association with a tracheoesophageal fistula. Even after vascular repair, the cartilages may not return to their normal appearance for many years, due to chronic changes of the cartilage from general sclerosis or scarring.

The gold standard in diagnosing tracheomalacia is using a flexible bronchoscopy. Other helpful tests include airway fluorography and also rigid bronchoscopy using either just a Hopkins telescope or a very small bronchoscope. The bronchoscopy has to be performed with the patient spontaneously ventilating; otherwise, the diagnosis might not be evident, due to the positive airway pressure stenting the airway, or if apneic techniques are adopted, the loss of the respiratory drive reduce, the severity of the tracheomalacia.

Tracheomalacia is generally self-limiting because adequate growth of the airway diameter eliminates the symptoms by the time the patient is 2–3 years old.[55,56] Therefore, treatment is aimed at preventing complications for tracheomalacia such as atelectasis. In severe cases, continuous positive airway pressure (CPAP) may be necessary until the infant outgrows the tracheomalacia. Furthermore, in some cases, a tracheostomy is performed to delivery CPAP to the distal trachea.[53]

When vascular compression is noted, aortopexy may be used to alleviate the pressure of the trachea and reduce the effect of tracheomalacia.[53,56,57] Internal airway stenting is another method but comes with a long list of downsides, including granulation tissue formation, risk of foreign body reaction, and extrusion, which could be fatal if the compression is from a major vessel. For that reason, caution is warrant while selecting patients for internal airway stenting.[58,59]

Vascular anomalies

In these disorders, the trachea is inherently normal. However, due to a large vessel extrinsically compressing it, the tracheal wall is deformed. Vascular anomalies are due to abnormal development of the branchial arches. They are rare anomalies and frequently coexist with other cardiac anomalies. Abnormalities that can occur in vessels include abnormal positioning of the aorta, anomalous branching, interrupted arches, or anomalous origin of the pulmonary artery.

The presenting symptoms depend on the degree of airway compression. Symptoms range from asymptomatic to severe life-threatening airway distress. Frequent presentations include recurrent pneumonias, stridor, dysphagia, and cough. Occasionally, these infants hyperextend their neck to stretch their trachea, which results in a widening of the diameter of the airway. Patients can also present as acute life-threatening events (ALTEs), reflex apnea, or cyanotic spells.[60,61]

When suspected on a bronchoscopy the diagnosis can be confirmed using an echocardiography, MRI, or CT scan. Additionally, angiography may help in the diagnosis.[62–64]

The most common vascular abnormality is an aberrant innominate artery compressing the anterior wall of the trachea.[65] The second most common is double aortic arch. This anomaly results in a double compression: on the trachea anteriorly and the esophagus posteriorly. Other anomalies include pulmonary artery sling in which the left pulmonary artery passes between the trachea and the esophagus, resulting in right bronchus and distal tracheal posterior compression. It is also associated with complete rings of the trachea. Aberrant right subclavian artery, which is also known as arteria lusoria, is a condition in which the right subclavian artery arises as a fourth branch (instead of being the first branch of the aortic arch). It passes posterior to the esophagus in 80% of cases to reach to the right side. It is associated with a right nonrecurrent laryngeal nerve.[66]

The treatment in these cases is dictated by the patient's airway and dysphagia symptoms. If not severe, the patient could be observed safely,[55] but occasionally, aortopexy, dividing the arches, or vascular rerouting can be performed to alleviate the compression if the patient's symptoms are severe.

Complete tracheal rings

Development of abnormal tracheal rings occurs after 8 weeks of gestation. The tracheal cartilages are fused posteriorly, and there is absence of the posterior membranous trachea and the typical C-shaped rings. It is a rare condition representing less than 1% of all laryngotracheal stenosis. This anomaly may involve a few rings up to the entire length of the trachea.[67]

Patients present with dyspnea, increased work of breathing, and biphasic or expiratory stridor (depending on the location and the length of the segment). In patients with <50% tracheal stenosis, symptoms may be mild, or the patient may be asymptomatic.[68]

Plain chest x-ray may provide clues as to the stenosis due to a narrow air column. Other radiological tests including CT and MRI are helpful especially when looking for associated disorders (e.g., pulmonary sling). The gold standard remains a rigid bronchoscopy to diagnose the anomalies and measure the length of the stenotic segment.[67,68]

Infants with mild symptoms can be treated medically by controlling their GERD and respiratory disorders. More severe cases generally require a surgical intervention. Surgical options vary depending on the symptoms, degree of stenosis, and location of the stenotic segment. Endoscopic approaches, using laser, dilation, and possibly stenting, are reserved for short segments.[69] Open procedures are used for failed endoscopic approach, severe stenosis, and thick or long segments.[67,70–72] Primary resection and anastomosis is a very good option for short segments with severe stenosis.

For longer segments, tracheoplasty with alloplastic or pericardial grafts was considered a classic technique, which is currently less utilized due to the higher risks of complications. Instead, slide tracheoplasty is currently the procedure of choice for most airway surgeons to treat long-segment complete tracheal rings. In these surgeries, extracorporeal myocardial oxygenation (ECMO) may be necessary while performing the procedure, especially in children with long- or distal-segment tracheal stenosis.[70–72]

Tracheal atresia and agenesis

This is a rare usually fatal anomaly of the airway. The tracheal is either completely absent (agenesis) or considerably underformed (atresia). This means that the communication between the lungs and larynx is missing. Therefore, newborns are only able to survive if there is an alternate way for the air to go to the lungs, e.g., bronchoesophageal fistula. Surgical repair can be attempted, but in general, the prognosis is poor.[73,74]

Congenital thoracic deformities

KONSTANTINOS PAPADAKIS AND ROBERT C. SHAMBERGER

INTRODUCTION

Congenital thoracic deformities present a wide spectrum of abnormalities. They include a myriad of complete and incomplete sternal defects: thoracic ectopia cordis, thoracoabdominal ectopia cordis (Cantrell pentalogy), and bifid sternum. The most frequent are the deformities of the ribs—including pectus excavatum, pectus carinatum, and Poland syndrome. Asphyxiating thoracic dystrophy (Jeune syndrome) and spondylothoracic dysplasia (Jarcho–Levin syndrome) pose the greatest surgical challenges.

ECTOPIA CORDIS

The first report as described of an exposed heart through a split sternum was described in 1671–1672, by N. Stensen.[1] Later reports, by Weese in 1818[2] and Todd in 1836,[3] proposed classifications of this disorder.

Infants with this anomaly are best classified by the precise location of the heart: cervical (3%), cervicothoracic, thoracic (60%), thoracoabdominal (7%), and abdominal types (30%).[2,3] In cervical ectopia cordis, the heart protrudes at the base of the neck and occurs in association with other severe deformities of the fetus. The cervical type is not compatible with life.

Thoracic ectopia cordis includes infants with an entirely bare heart that is outside the thorax, with cephalic orientation of the cardiac apex. It protrudes through a central sternal cleft and lacks a parietal pericardium and overlying skin. This condition may be associated with a separate epigastric omphalocele or upper abdominal wall defect. Thoracic ectopia cordis must be distinguished from cleft sternum, in which the heart is covered by normal skin in an orthotopic intrathoracic position and is anatomically normal.

In thoracoabdominal ectopia cordis, also known as pentalogy of Cantrell, the heart is covered by skin or an omphalocele-like membrane. It is associated with a constellation of anomalies. The classic pentalogy includes the following: (1) a midline, supraumbilical abdominal wall defect; (2) a defect of the lower sternum; (3) a deficiency of the anterior diaphragm (absence of septum transversum); (4) a defect in the diaphragmatic pericardium; and (5) congenital intracardiac defects. All five anomalies may not be present, and there can be an incomplete expression of the syndrome.[4] In contrast with thoracic ectopia cordis, the heart is covered and lacks severe anterior displacement and cephalic orientation. The world literature on ectopia cordis has been extensively reviewed previously.[5]

Ectopia cordis is diagnosed by prenatal ultrasound from early stages of gestation, which facilitates perinatal preparation.[6,7] Associated intrinsic cardiac anomalies and other anomalies can be defined by in utero studies in order to facilitate parental discussion regarding prognosis.

The cause is unknown. There has been a weak association with trisomy 18,[8–10] triploidy, and familial X-linked inheritance. The incidence is 5.5–7.9 per 1 million live births.

Thoracic ectopia cordis

The presentation of the heart, naked and beating upon the chest wall, has stimulated many case reports (Figure 36.1). Surgical repair has been described,[11,12] but long-term successes are limited by a combination of associated intrinsic cardiac malformations and abnormal rotation of the heart with the apex pointing cephalad.[13] The first successful repair of ectopia cordis was achieved by Koop in 1975, as reported by Saxena.[14] An infant with a normal heart had skin flap coverage at 5 hours of age, with inferior mobilization of the anterior attachments of the diaphragm. At 7 months of age, an acrylic resin of Dacron and Marlex mesh was inserted to widen the sternal cleft with primary skin closure. Necrosis of the skin flaps complicated the postoperative course; the infection of the prosthetic material required its subsequent removal. The child's long-term survival has been reported.[15] Lillehei (as reported by Hornberger et al.[16]) achieved successful repair of the only infant with an intrinsic cardiac

Figure 36.1 Infant with thoracic ectopia cordis. Heart lies anterior to the thoracic cavity, and apex is directed cephalad.

anomaly, tetralogy of Fallot with pulmonary atresia. A combination of thoracic ectopia cordis and separate omphalocele with an intervening bridge of normal skin can be particularly difficult to manage. In this group of patients, adequate skin and abdominal wall components, to cover both areas, are lacking, and no survivors exist. The unifying theme of successfully managed cases is construction of a partially anterior chest cavity surrounding the heart and avoidance of attempts to return the heart to an orthotopic location (Table 36.1).[16–18]

For a successful outcome in infants with thoracic ectopia cordis, early definition of the associated cardiac malformation is necessary. Prenatal workup with echocardiography and magnetic resonance imaging (MRI) is often more successful than postnatal attempted ultrasonography, which is complicated by direct motion artifact of the heart and interference by air. Cardiac catheterization with angiography may be required in infants not diagnosed by antenatal studies. If the cardiac malformation is correctable, the infant should be taken from the cath lab directly to the operating room for cardiac repair. Some form of cardiac enclosure must then be provided. Use of prosthetic materials is associated with a high incidence of sepsis and death, especially when prosthetic materials have been used inside the cardiac repair.

Thoracoabdominal ectopia cordis (Cantrell pentalogy)

In 1958, Cantrell and coworkers[19] reported a series of a previously described congenital syndrome characterized by the following: (1) a midline, supraumbilical abdominal defect; (2) a defect of the lower sternum; (3) a deficiency of the anterior diaphragm; (4) a defect in the diaphragmatic pericardium; and (5) congenital intracardiac defects (Figure 36.2). A complete summary of all reported cardiac anomalies has been presented.[5] All five anomalies may not be present, and there can be an incomplete expression of the syndrome.[4,20] This condition was precisely described by Wilson in 1798, with the first repair attempted by Arndt in 1896 and the first successful repair by Weiting in 1912.[21–23] The anomaly was reviewed by Major in 1953 and later by Cantrell et al. in 1958, for whom the anomaly has ironically been named.[19,24] The pathogenesis of the defects is unclear, but the occurrence of this syndrome is likely sporadic. X-chromosome recessive inheritance has been postulated. There have been associated cases with trisomy 13, 18, and 21, as well as posterior fossa anomalies, hemangioma, arterial lesions, cardiac abnormalities/coarctation of the aorta, and eye anomalies (PHACES) syndrome.[25] Multiple etiologies, including viral infection, maternal abuse of beta-aminopropionitrile, and chlorine inhalation, have also been implicated.[26,27] The occurrence rate is less than 1 out of 100,000 live births, and the condition more frequently affects males (2:1), while affected females have more severe symptoms. Due to the variable nature of expression, Toyama[4] suggested further subclassification of this syndrome: Class 1, definite diagnosis with all five defects present; Class 2, probable diagnosis with four defects noted (including intracardiac and ventral abdominal wall abnormalities); and Class 3, incomplete expression. Early prenatal diagnosis in the first trimester, with 2-D and 3-D sonography, is helpful for parental counseling.[28–30]

The successful management of thoracoabdominal ectopia cordis necessitates a multispecialty approach from the establishment of the antenatal diagnosis to the completed staged repairs. Immediate neonatal intervention is required in patients with a large upper omphalocele and lower sternal cleft (Figure 36.3).[31] In a staged repair, primary closure, split-thickness skin graft, cadaveric skin graft, or prosthetic material sutured to the skin edges must be achieved to prevent fluid

Table 36.1 Successful repairs of ectopia cordis

Author	Year	Cardiac lesion	Method of sternal closure
Koop	1975	None	Skin flap closure at 5 hours. Acrylic resin applied to sternal cleft at 7 months (Saxena[14]).
Dobell et al.[17]	1982	None	Perinatal skin closure in one stage. Second-stage repair with autologous rib grafts.
Amato et al.[18]	1988	None	Skin flaps mobilized; diaphragm moved inferiorly. Gortex membrane used to close defect with skin flaps over it. Child survived but died of aspiration at 11 months of age.
Lillehei	1996	Tetralogy of Fallot	Perinatal skin flap closure (Hornberger et al.[16]). Blalock–Taussig shunt at 4 days of life and complete repair at 2 years of age. No prosthetic tissue coverage.

Figure 36.2 Newborn male with Cantrell pentalogy. Flaring of the lower thoracic cavity is present with a large epigastric omphalocele. The septum transversum and the inferior portion of the pericardium were absent. (From Welch K., Chest Wall Deformities, *Pediatr Surg* 1980, Eds. Holder TM and Ashcraft, KW:162–82. By permission of W.B. Saunders Co., Philadelphia.)

losses, cardiac dessication, or trauma to the heart. Subsequent intervention may be needed to gradually reduce the heart to a more anatomic position. Multiple procedures have been suggested to try to accommodate the heart; these include partial or total excision of the thymus, repair of the diaphragmatic defect, plication of a hemidiaphragm, or division of the costal cartilages. Some have even advocated that a left lower lobectomy be performed in order to better accommodate the heart in the left pleural space. In all procedures, care must be taken to prevent kinking of the great vessels and to avoid phrenic nerve damage. Other options include the use of alloplastic materials, such as creation of methyl methacrylate struts shaped as ribs and spaced to allow for future growth of ribs and thorax.

BIFID STERNUM

Sternal clefts are malformations caused by the failure of fusion of the sternal elements. The etiology of sternal cleft deformity is unknown. There are studies on ventral body

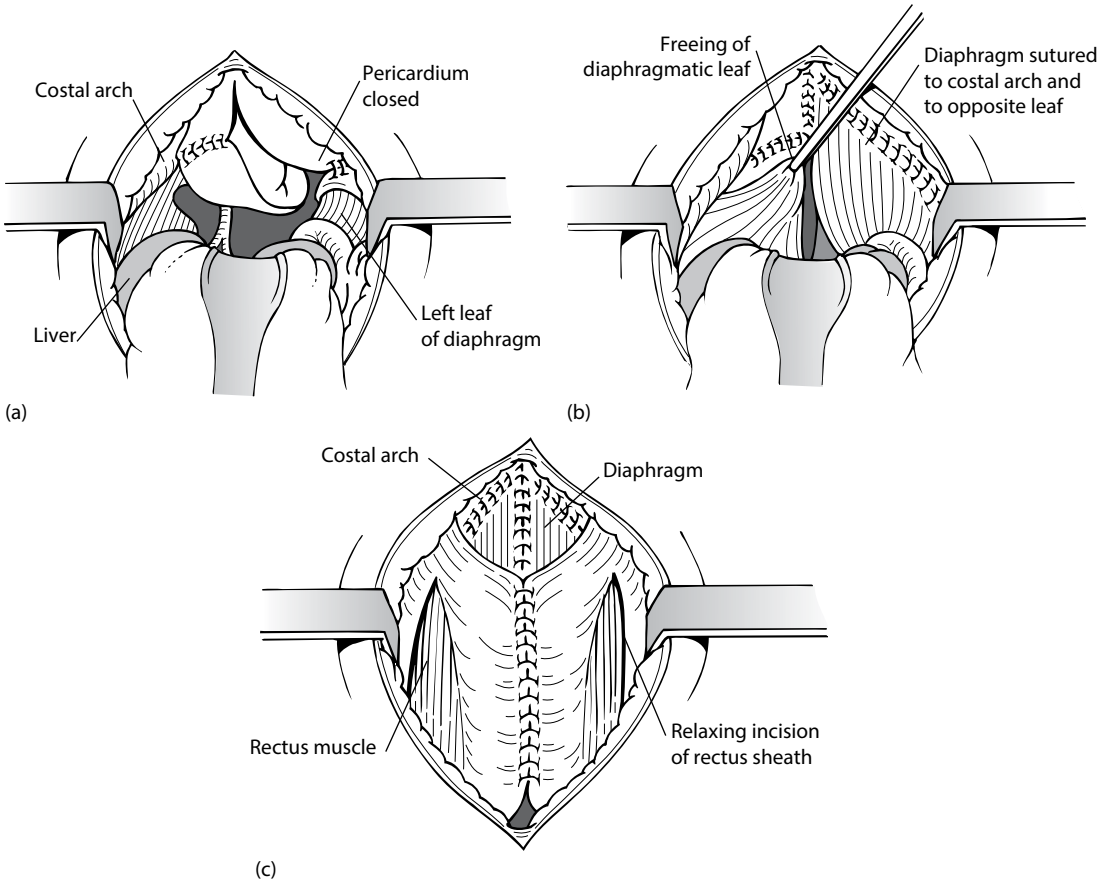

Figure 36.3 Repair of pentalogy of Cantrell is depicted. **(a)** The pericardium is closed after appropriate lateral and inferior dissection to the vena cava. The right and left dorsal leaves of the diaphragm, which are widely separated, are identified. The liver is retracted inferiorly after division of the falciform ligament. **(b)** Pedicles of the diaphragm are developed from each side and transposed medially. They are sutured together and to each costal arch. **(c)** After diaphragmatic closure, the falciform ligament is reconstructed. Closure continues by advancement of the anterior sheath of the rectus muscle to the midline. Lateral relaxing incisions are often required. Parietal repair can be accomplished at the time of cardiac correction. Prosthetic material may be required to obtain closure of the abdominal component of the repair. (From Welch K., Chest Wall Deformities, *Pediatr Surg* 1980, Eds. Holder TM and Ashcraft, KW:162–82. By permission of W.B. Saunders Co., Philadelphia.)

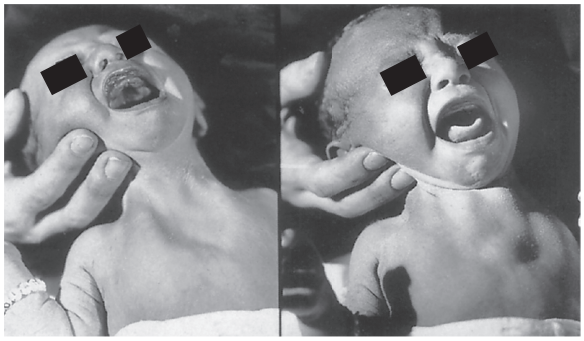
development in mice that indicate that impairment in Hoxb gene expression may be a possible factor.[32] Cleft sternum may be complete or incomplete and results from failure of the mesenchymal plate fusion process at the eighth week of gestation. No familial predisposition has been described. Alcohol intake and methylcobalamine deficiency have been implicated. There is a slight female predominance. Sternal clefts can be associated with cervicofacial hemangiomas (vascular dysplasia) and PHACES syndrome.[33,34]

In all cases, there is a sternal separation and skin coverage of the midline defect, intact pleural envelopes, and a normal diaphragm. Omphalocele does not occur in association with this anomaly, and the condition causes little difficulty other than a dramatic increase in the deformity with crying or Valsalva maneuver (Figure 36.4). The sternal defect involved an upper cleft in 46 patients, an upper cleft to the xiphoid in 33 patients, and a complete cleft in 23 patients.[5] The cleft involved the lower sternum in only five reported cases. A total of 69 repairs have been reported, 25 with primary closure. None of the infants and children had intrinsic congenital heart disease.

Most authors now recommend surgical treatment in the newborn period after all other anomalies are ruled out and addressed (Figure 36.5).[35,36] Recent studies have shown no difference in surgical outcome between primary closure and



(a)

(b)

Figure 36.4 Newborn infant with a bifid sternum. **(a)** Vigorous crying produces retraction at the defect with inspiration (left) and protrusion with exhalation or Valsalva maneuver (right). **(b)** Following repair, normal configuration of the sternum is present.

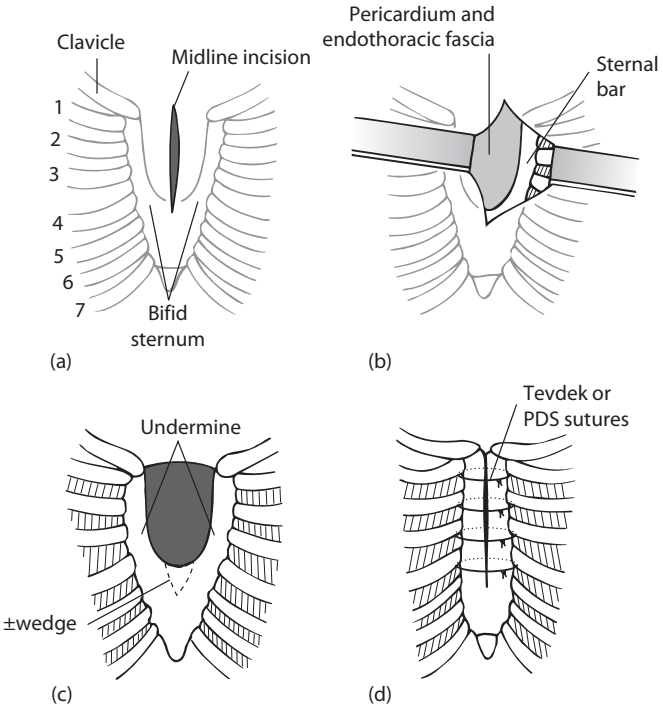


Figure 36.5 **(a)** Repair of bifid sternum is best performed through a longitudinal incision extending the length of the defect. **(b)** Directly beneath the subcutaneous tissues, the sternal bars are encountered with pectoral muscles present lateral to the bars. The endothoracic fascia and pericardium are just below these structures. **(c)** The endothoracic fascia is mobilized off the sternal bars posteriorly with blunt dissection to allow safe placement of the sutures. Approximation of the sternal bars may be facilitated by excising a wedge of cartilage inferiorly. Repair is best accomplished in the neonatal period because of the flexibility of the chest wall. **(d)** Closure of the defect is achieved with 2-0 Tevdek or PDS sutures. (With kind permission from Springer Science+Business Media: *Pediatr Surg Int*, Sternal Defects, 5, 1992, 156–64, Shamberger R. and Welch K.)

treatment with prostheses.[37] No reports of recurrence or delayed healing have been encountered. In older children, reconstruction of the anterior chest wall using multiple oblique sliding chondrotomies leaving the perichondrium intact was reported by Sabiston[38] and subsequently by others.[39] This technique is useful in older infants and children with a less flexible chest wall and a wide defect. Closure employing composite cartilage grafts from the costal arch or reversed sternal plates[40] or prosthetic materials such as Marlex, Teflon, or Surgisis[41] mesh have also been reported, but these methods can be avoided with repair of the infants in a timely fashion.

Shamberger and Welch[5] reviewed their experience with sternal defects at Boston Children's Hospital, Massachusetts, USA. A total of 16 patients with sternal defects were identified, 5 with ectopia cordis, 8 with thoracoabdominal ectopia cordis, and 3 with cleft sternum. Thoracic ectopia cordis was uniformly fatal in their series; thoracoabdominal ectopia cordis was fatal in five of eight cases, and bifid sternum was successfully repaired in all three cases in infancy.

PECTUS EXCAVATUM

Pectus excavatum (funnel chest or *trichterbrust* [German]) is a depression of the sternum and lower costal cartilages. It is generally identified within the first year of life (in 86% of patients), and in many infants, it is noted at birth.[42] The extent of sternal and cartilaginous deformity is quite variable, but generally consists of posterior displacement of the sternum below the insertion of the second costal cartilage. The first and second costal cartilages are generally normal in contour, whereas the third to seventh are curved posteriorly to join the sternum. The ossified portion of the rib is normal in configuration in infancy. In infants, the extreme flexibility of the costal cartilages results in remarkable changes in the deformity with vigorous respiration or crying. Self-limited deformities are either gone or vastly improved by 3 years of age. Repairs should be avoided in all infants younger than 2 years of age. We generally delay open repair until children have achieved much of their chest wall growth to avoid the reported occurrence of acquired thoracic dystrophy in younger children following repair.

Pectus excavatum may occur as frequently as 1 in 300–400 live births.[43] The etiology of pectus excavatum is unknown. A family history of some type of anterior thoracic deformity is present in 37% of patients.[42] Scoliosis is identified in up to 15% of patients with pectus excavatum, usually in children with an asymmetric thoracic deformity, but it is generally not seen in infancy. Patients with Marfan syndrome have a high incidence of associated chest wall deformities, often in the most severe form and usually accompanied by scoliosis.

PECTUS CARINATUM

Pectus carinatum, the anterior protrusion deformity of the chest, is much less frequent than pectus excavatum, comprising 16% of our combined series.[44] A spectrum of protrusion deformities exist, and these are often divided into four types. The most frequent type consists of anterior displacement of the sternum with symmetric concavity of the costal cartilages laterally. Asymmetric deformities with anterior displacement of the costal cartilages on one side and a normally positioned or oblique sternum and normal cartilages on the contralateral side are less common. "Mixed" lesions have a carinate deformity on one side and a depression or excavatum deformity on the contralateral side, often with sternal obliquity. Most unusual are the upper "pouter pigeon" or chondromanubrial deformities, with protrusion of the manubrium and second and third costal cartilages and relative depression of the body of the sternum.

The etiology of pectus carinatum is unknown. There is overgrowth of the costal cartilages, with forward buckling and anterior displacement of the sternum. As with pectus excavatum, there is a clear-cut increased family incidence, suggesting a genetic basis. In a recent review, 26% of patients had a family history of chest wall deformity, and 12% had a family history of scoliosis.[44] Pectus carinatum is much more common in boys than girls, with a ratio of 4:1. Only the upper pouter pigeon deformity is associated with congenital heart disease, in 18% of cases.[45]

In contrast to pectus excavatum, patients with pectus carinatum have a much later appearance of the deformity. In a recent review, only one-sixth of the patients were noted to have a carinate deformity within the first year of life, and in almost half, it was noted after the onset of the pubertal growth spurt at 11 years of age.[44] The deformity, which may be mild at birth, often worsens rapidly during puberty. Because of mild deformity at birth and flexible costal cartilages, this deformity is rarely repaired during the first 2 years of life and is probably best repaired in the early teenage years. Bracing is effective in correcting the protrusion in the majority of patients, avoiding the need for surgical intervention.

POLAND SYNDROME

Poland, in 1841, described congenital absence of the pectoralis major and minor muscles, associated with syndactyly.[46] This is a diverse syndrome, often involving chest wall and breast deformity as well as serious ipsilateral hand and arm anomalies. A Poland–Möbius variant has been described, with dextrocardia and facial weakness.[47] The extent of thoracic involvement may range from hypoplasia of the sternal head of the pectoralis major and minor muscles with normal underlying ribs, to complete absence of the anterior portions of the second to fourth ribs and cartilages, often called the second to fourth rib syndrome. Breast involvement is significant in females, ranging from mild degrees of breast hypoplasia to complete absence of the breast (amastia) and nipple (athelia). Hand deformities are frequent and occurred in the patient described by Poland. They may include hypoplasia (brachydactyly), fused fingers (syndactyly), and mitten or claw deformity (ectromelia).

This condition is present at birth and has an estimated incidence of 1 in 30,000 to 1 in 32,000.[48] The etiology of this deformity is unknown, but it affects the developing somatic tissue for the entire limb bud and chest wall. Abnormalities in the breast can be recognized at birth by the absence of the underlying breast bud and hypoplastic, often superiorly displaced nipple. Males predominate by at least 3:1 and show a right-sided predilection. Females show less sidedness. Familial cases, in either gender, occur equally on the left and the right. In our series, chest wall reconstruction was required in 10 out of 41 cases, but never in infancy.[49]

THORACIC DEFORMITIES IN SKELETAL DISORDERS

Congenital asphyxiating thoracic dystrophy (Jeune disease)

Jeune, in 1954, first described a pair of siblings with a narrow rigid chest and multiple cartilage anomalies.[50] The syndrome is also known as asphyxiating thoracic dysplasia (ATD)

and thoracic–pelvic–phalangeal dystrophy.[51] This is a rare autosomal recessive disorder.[52,53] Other manifestations include dwarfism with short ribs and short limbs—with radiographic changes in the ribs and pelvis. There is some association with abnormalities of the kidneys, liver, pancreas, and retina.[54] Variable skeletal and radiographic severity occurs in this syndrome. Its most prominent feature is a narrow "bell-shaped" thorax and protuberant abdomen. The thorax is narrow in both the transverse and sagittal axes and has little respiratory motion due to the horizontal direction of the ribs (Figure 36.6). The ribs are short and wide, and the splayed costochondral junctions barely reach the anterior axillary line. The costal cartilage is abundant and irregular like a rachitic rosary. Microscopic examination of the costochondral junction reveals disordered and poorly progressing endochondral ossification, resulting in decreased rib length.

The syndrome has variable expression and extent of pulmonary involvement, resulting in a wide range of survival.[55] Lung hypoplasia is due to a restricted thoracic cage and may be the cause of death in infancy. The most common presentation is hypoventilation, caused by impaired chest expansion. Frequency of the condition is approximately 1 per 100,000–130,000 live births.[56] Reports have described the ability to diagnose fetuses suspected to have Jeune syndrome with prenatal ultrasonography.[57,58] The pathological findings in autopsy cases are variable and show a range of pulmonary development; in most cases, the bronchial development is normal, and there is a variable decrease in alveolar divisions.[59]

There have been many surgical attempts to treat this disorder. The main goal of surgery is to expand thoracic volume and allow improved lung expansion. Early surgical interventions were reported by Barnes and colleagues, Karjoo and coworkers, and Mustard.[43,60,61] Early repairs reported attempts at thoracic enlargement by splitting the sternum, which was then held apart by a variety of graft materials. Authors used either autologous tissue, such as rib grafts or iliac crest bone, or synthetic materials including methyl methacrylate,[62] and stainless steel wires. There are multiple reports of initial improvement in lung ventilation, but subsequent growth failure of the chest resulted in recurrent respiratory distress.[62,63] Davis and coworkers,[64] in 1995, described a new lateral thoracic expansion (LTE) technique for ATD. New bone formation is documented 3 weeks after the procedure. LTE has been successfully performed on a preterm infant in the neonatal period.[65] Long-term follow-up for this procedure has not been reported, however.

Campbell and coworkers[66] have described a vertical expandable prosthetic titanium rib (VEPTR) procedure for use in a variety of pediatric conditions of "thoracic insufficiency syndrome." Vertically oriented titanium struts are attached to ribs and/or transverse processes of the spine and progressively lengthened with a series of surgical procedures to allow progressive expansion of the chest cavity. Computed tomography (CT) imaging studies have documented postoperative increase in chest volume; however, improvements in pulmonary function tests have not been demonstrated. Few patients with Jeune syndrome[67] have had VEPTR procedures. In one series, 9% of those treated

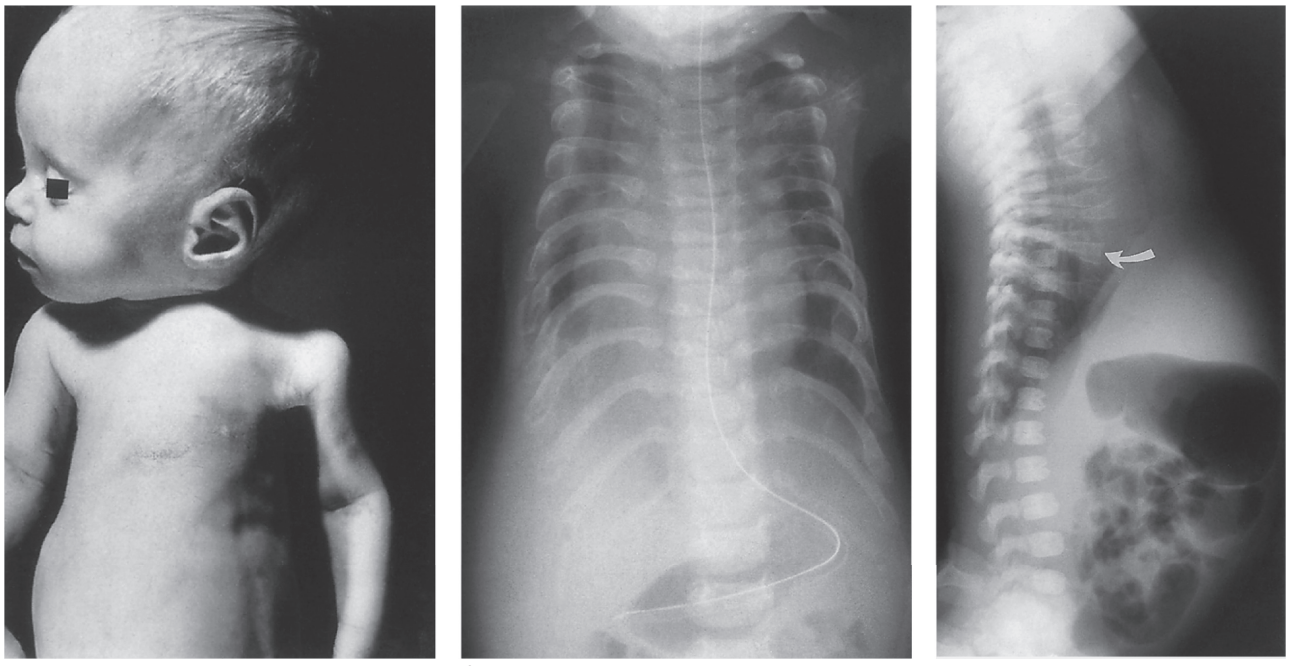

Figure 36.6 Infant with asphyxiating thoracic dystrophy (Jeune syndrome). **(a)** Clinical photograph demonstrates small size of thorax relative to infant. **(b)** Radiograph shows the short horizontal ribs and narrow thorax with limited lung volumes. **(c)** Lateral radiograph demonstrates the endings of the bony ribs at the midaxillary line and the abnormal costochondral junctions (arrow).

with VEPTR had Jeune syndrome, and all died within 2 years of the procedure—two from respiratory complications, one from renal failure, and one from liver failure.[68] The ultimate results of all surgical attempts will depend on the degree of underlying pulmonary parenchymal impairment of the infants. Respiratory failure is the most common cause of death for infants under 2 years of age and renal failure for deaths between the ages of 3 and 10 years of age.[69]

Spondylothoracic dysplasia (Jarcho–Levin syndrome)

Spondylothoracic dysplasia is an autosomal recessive deformity characterized by short-trunk dwarfism associated with multiple vertebral and rib malformations.[70] The ribs have a crab-like appearance (Figure 36.7). Death occurs early in infancy from respiratory failure and pneumonia. Patients have multiple alternating hemivertebrae, which affect most of the thoracic and lumbar spine. The ossification centers rarely cross the midline. Multiple posterior fusions of the ribs as well as remarkable shortening of the thoracic spine result in a crab-like radiographic appearance of the chest. One-third of the patients with this syndrome have associated malformations including congenital heart disease and renal anomalies. Its occurrence has been reported primarily in Puerto Rican families (15 out of 18 cases).[71] Bone formation is normal in these patients. Successful prenatal diagnosis can be established by sonographic examination.[72] Thoracic deformity is secondary to the spinal anomaly, which results in close posterior approximation of the origin of the ribs. The VEPTR procedure has been successfully performed in the neonatal period for this highly lethal syndrome.[73] Spondylothoracic dysplasia has a mortality rate approaching 50% from respiratory complications due to thoracic insufficiency syndrome. Most infants with this syndrome succumb before 15 months of age.[74] In spite of severe restrictive respiratory disease, adult survivors of spondylothoracic dysplasia appear to do well clinically for unknown reasons.[75]

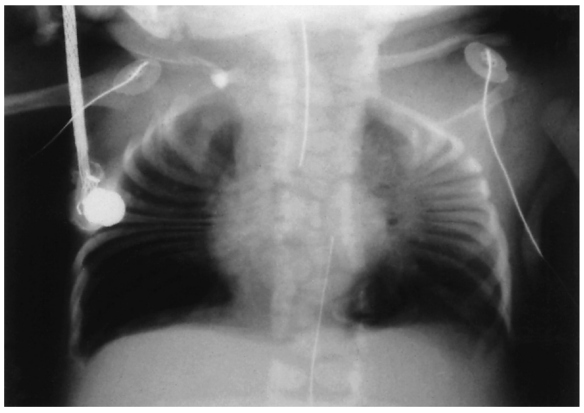

Figure 36.7 Radiograph of infant with spondylothoracic dysplasia (Jarcho–Levin syndrome). Severe abnormality of the spine is apparent with multiple hemivertebrae and the crab-like ribs with close approximation posteriorly and splaying out anteriorly.

Mediastinal masses in the newborn

ISRAEL FERNANDEZ-PINEDA AND STEPHEN J. SHOCHAT

Mediastinal masses in the newborn represent a wide variety of congenital and neoplastic lesions, which can present interesting diagnostic and therapeutic challenges. However, despite the heterogeneous makeup of this group of lesions, an accurate preoperative diagnosis can usually be established on the basis of the location of the mass. Although many of these mediastinal masses may grow in utero and appear quite prominent on prenatal ultrasound, watchful waiting is recommended unless the fetus is severely compromised. Indications for prenatal intervention may include compression from the mass on the esophagus that may lead to polyhydramnios; compression on the mediastinal lymphatics, veins, and heart that may lead to hydrops and heart failure; and compression on the lungs that may lead to pulmonary hypoplasia and respiratory failure after birth.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of mediastinal masses in newborns and infants is simplified if the mediastinum is arbitrarily separated into three compartments (Figure 37.1). For the purpose of this discussion, the mediastinum will be partitioned as follows: the anterior mediastinum lies anterior to the heart and lung roots and contains the thymus, anterior mediastinal lymph nodes, and rarely, a substernal extension of the thyroid and parathyroid. The middle mediastinum contains the trachea, bronchi, mediastinal lymph nodes, heart, and great vessels. The posterior mediastinum lies behind the heart and lung roots and contains the esophagus and intercostal sympathetic nerves. Anterior mediastinal masses include prominent thymus, ectopic thymus, thymic cysts/hyperplasia/tumors, teratomas, lymphatic malformations (LMs), lipomas, and lymphomas. Masses within the middle mediastinum include congenital vascular lesions such as double aortic arch, bronchogenic cysts, esophageal duplication cysts, neuroenteric cysts, lymphomas, and granulomatous infections within the mediastinal lymph nodes. Posterior mediastinal lesions include the tumors of neurogenic origin, undifferentiated sarcomas, congenital foregut duplications, and extralobar sequestrations.

The age of the patient at the time of diagnosis is extremely important, since certain masses have a predilection for younger infants and others are predominantly seen in older children and adolescents. In newborns and children under 2 years of age, the most common mediastinal mass is the neuroblastoma within the posterior mediastinum. In addition, thymic hyperplasia and bronchogenic cysts are seen predominantly in children less than 2 years of age. The various lymphomas are the most common mediastinal masses seen in children older than 2 years.

The presenting signs and symptoms in newborns and infants with mediastinal masses are variable:

- Acute respiratory distress
- Fever
- Cough
- Shortness of breath
- Stridor
- Cervical adenopathy
- Superior vena cava syndrome
- Horner syndrome
- Asymptomatic

Infants under 2 years of age frequently present with signs of tracheal compression (Figure 37.2) and acute respiratory distress. This is due to the smaller, softer, more pliable tracheobronchial tree in infants as well as the fact that they do not have a fixed mediastinum, so that large mediastinal masses can cause a significant shift of the mediastinum with compromise of the contralateral hemithorax. Older children will present with symptoms of fever, cough, and shortness of breath. Superior vena cava obstruction is rare in children but is occasionally seen. Horner syndrome may be the presenting finding in infants with neurogenic tumors of the posterior mediastinum. Asymptomatic mediastinal masses are seen in children of all ages and are frequently noted on a chest x-ray performed for a mild upper respiratory infection or are discovered incidentally following imaging studies for symptoms unrelated to the mediastinal mass.

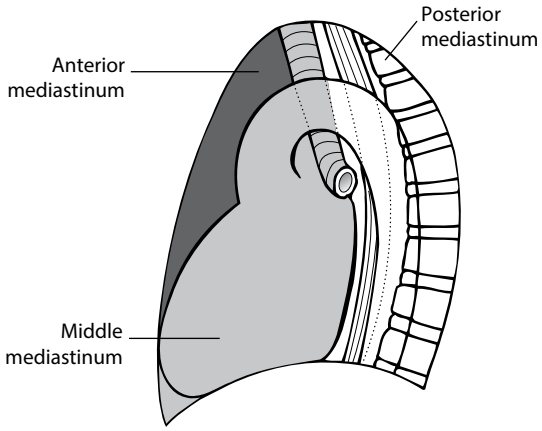

Figure 37.1 Compartments of mediastinum.

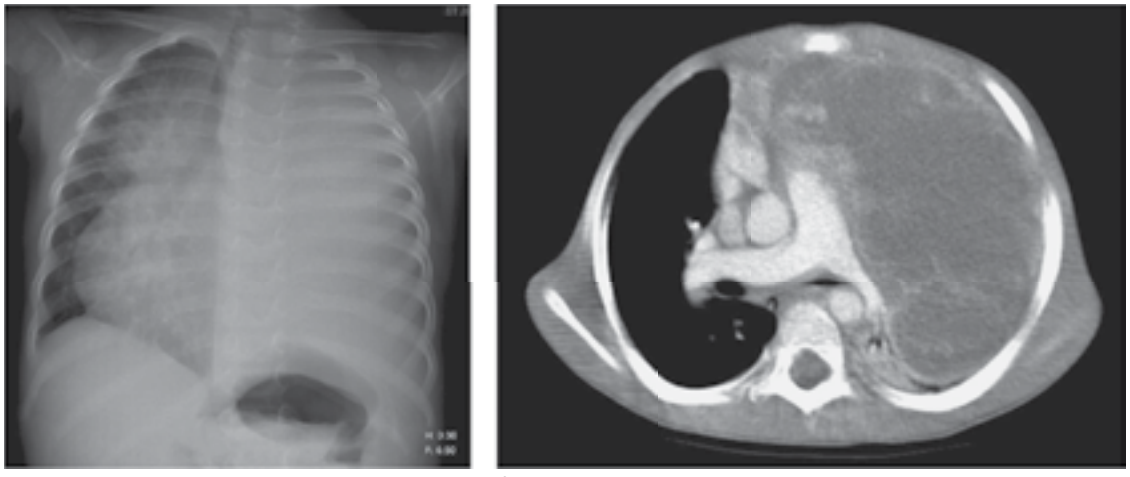
DIAGNOSIS

A systematic approach to the diagnosis of a mediastinal mass in the newborn is imperative and may include the following:

- Posteroanterior–lateral chest x-ray
- Barium swallow
- Ultrasonography (US)
- Computed tomography (CT)/angio-CT scan
- Magnetic resonance imaging (MRI)/magnetic resonance angiography (MRA)
- Bone marrow–lymph node biopsy
- Skin test—complement fixation
- Serum markers—alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG)
- Urinary catecholamines
- Metaiodobenzylguanidine (MIBG)

The goals of diagnostic imaging evaluating a mediastinal mass include the following: (1) identifying the characteristics and origin of the mass within the mediastinum; (2) delineating the extension; and (3) providing a differential diagnosis. The most helpful diagnostic technique in this age group is still the chest x-ray in the posteroanterior and lateral projections, in order to localize the position of the mass. Vertebral anomalies associated with a mediastinal mass in a newborn or infant should raise suspicion of the so-called neuroenteric variety of enterogenous cyst, which communicates with the meninges. Calcification within a posterior mediastinal mass suggests the presence of a neuroblastoma, and anterior mediastinal teratomas frequently contain calcification and cystic areas. In cases of suspected enterogenous and bronchogenic cysts, the esophagogram may be of value. US of the chest can be particularly helpful in newborns and infants younger than 12 months. The unossified sternal and costal cartilages provide an acoustic window large enough to allow evaluation of anterior mediastinal masses such as thymic hyperplasia. Echocardiography should be performed to delineate the heart and great vessels if lesions of these structures are suspected. A CT scan should be reserved for difficult diagnostic dilemmas and for delineating anatomical boundaries in preparation for tumor resection. CT scan offers multiplanar reformations and 3-D reconstructions. MRI and MRA may be of help in differentiating masses of vascular origin from other mediastinal structures and may be helpful in infants with suspected thymic hyperplasia. In addition, MRI should be considered in cases of posterior mediastinal masses in order to detect intraspinous extension of dumbbell tumors. Cardiac MRI, with its excellent tissue characterization and wide field of view, may provide additional unique information.

A bone marrow aspiration/biopsy and cervical lymph node biopsy should be considered in children with middle mediastinal lesions and suspected lymphoma. Skin testing and complement fixation titers should be considered in infants with middle mediastinal masses to rule out granulomatous infections. AFP determination and HCG titers



(a) (b)

should be performed in children with anterior mediastinal masses if malignant germ cell tumors (GCTs) are suspected. Urinary catecholamine metabolites should be evaluated in infants with posterior mediastinal masses both for diagnosis and for postoperative follow-up in children with suspected neuroblastomas.

ANTERIOR MEDIASTINUM

The anterior mediastinum accounts for most of all mediastinal masses in newborns, with thymic hyperplasia as the most common anterior mediastinal mass (Figure 37.3). This diagnosis is usually not difficult as there is frequently a characteristic "sail" sign on routine chest x-ray. Recently, US has been very helpful in differentiating thymic hyperplasia from other mediastinal masses and should be considered in difficult cases. If definite confirmation of normal thymus cannot be made from radiographs and US imaging, a correct diagnosis can be confidently made with CT or MRI. Most GCTs in the newborn period and under 2 years of age are benign teratomas (Figure 37.4). CT or MRI typically shows well-encapsulated, complex masses with cystic and solid areas containing fat and irregular calcifications. These tumors tend to displace rather than invade adjacent structures, and surgical resection through a posterolateral thoracotomy is usually the preferred approach. LMs (Figure 37.5) also are observed in newborns and infants but usually have a cervical or axillary component, which makes this diagnosis obvious. LMs at this location are at risk of airway obstruction in newborns. Ex utero intrapartum treatment (EXIT procedure) involves partial delivery of the fetus with the fetal–placental circulation maintained. This allows for management of the obstructed fetal airway via direct laryngoscopy, bronchoscopy, tracheostomy, or surgical intervention. The EXIT procedure should be available for newborns with prenatal diagnosis of cervicothoracic mass. Malignant GCTs of the anterior mediastinum are usually seen in older children and adolescents, and many have an endodermal sinus or yolk sac component with an elevated serum AFP. AFP and HCG levels should be obtained in children with anterior mediastinal masses as these markers are helpful not only in diagnosis but also in following response to therapy. When the tumor is nonresectable, a biopsy rather than partial resection is followed by chemotherapy and delayed primary excision.

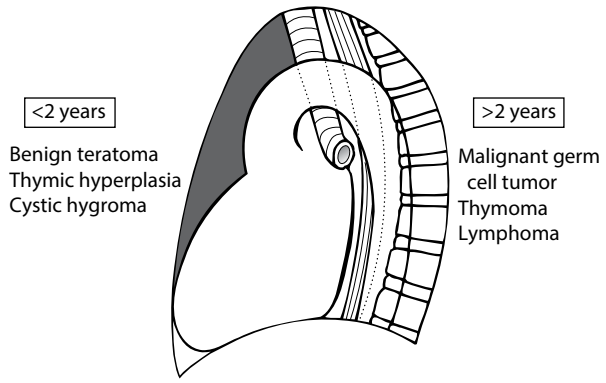

Figure 37.3 Anterior mediastinum.

MIDDLE MEDIASTINUM

Mediastinal foregut duplication cysts are uncommon congenital anomalies that result from developmental malformations of the embryonic foregut. They can be classified into three types: bronchogenic, esophageal duplication, and neuroenteric cysts. Bronchogenic cysts may be seen in all age groups but are the most frequent mass seen within the middle mediastinum in infants and children under 2 years of age (Figure 37.6). They are generally located in the subcarinal region and are frequently associated with a characteristic expiratory stridor due to accentuation of the obstruction of the lower trachea during expiration. Diagnosis may be difficult on routine chest x-ray, but there is usually a characteristic displacement of the esophagus on barium swallow (Figure 37.7). Bronchogenic cysts occasionally are intimately attached to the membranous

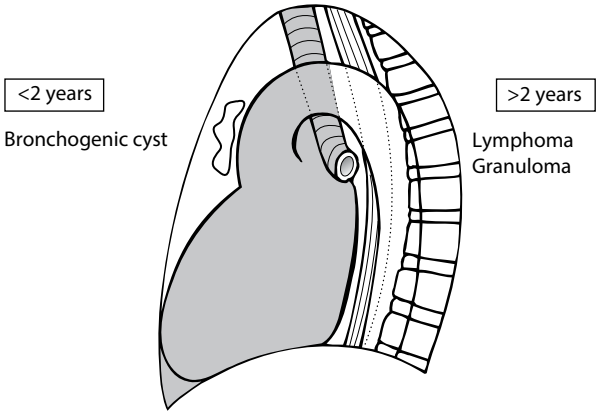

Figure 37.6 Middle mediastinum.

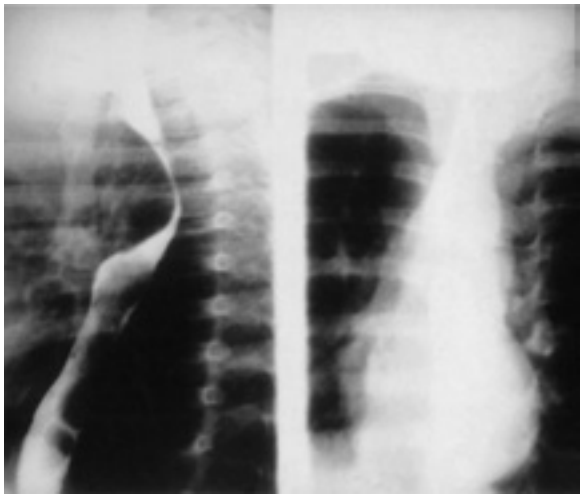

Figure 37.7 Bronchogenic cyst showing displacement of esophagus. Normal-appearing chest x-ray.

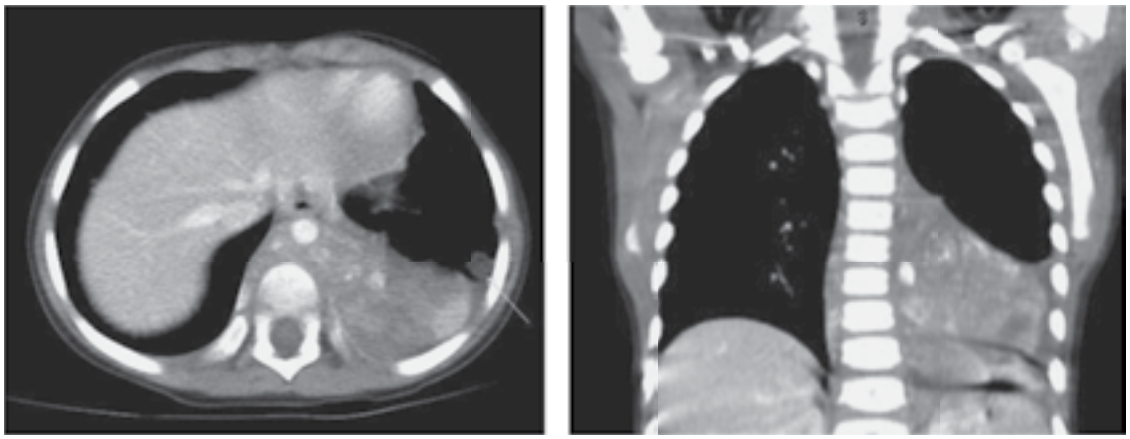
trachea, and if this is the case, a small portion of the cysts should be left attached to the trachea. Esophageal duplication cysts are typically located adjacent to the upper third of the esophageal wall, and dysphagia is the most common presenting symptom. Neuroenteric cysts, while rare, represent an interesting spectrum of lesions that may be seen in the middle and posterior mediastinum. They may be intimately associated with the esophagus and cause dysphagia, or they can contain gastric mucosa, which has been associated with peptic ulceration, perforation, and bleeding. Large cysts can have abdominal extensions and communicate with an intestinal duplication. Lymphadenopathy in the middle mediastinal compartment in children is most commonly due to either neoplastic or infectious processes. Lymphomas are the most frequent tumors involving the middle mediastinum over 2 years of age but are rarely seen in the newborn or infant. If the diagnosis of lymphoma is highly suspicious, one should be aware of the use of less invasive diagnostic tools, including examination of pleural fluid, bone marrow, or biopsy of peripheral lymphadenopathies. Granulomatous infections of the paratracheal, subcarinal, or hilar lymph nodes are occasionally seen and can usually be diagnosed by appropriate skin tests and complement fixation titers.

POSTERIOR MEDIASTINUM

The most common mass of the posterior mediastinum and in fact the most common mass in newborns is a posterior mediastinal neuroblastoma (Figure 37.8). Mediastinal neuroblastomas are interesting in that they seem to have a different biological behavior from intra-abdominal tumors. The majority of mediastinal neuroblastomas are localized or low-stage disease and have a favorable outcome following resection. These tumors are more often occult and are diagnosed on x-ray examination for other complaints. Respiratory distress due to compression or deviation of trachea is a feature in some cases. Thoracic neuroblastomas with dumbbell extension may present with neurological symptoms due to spinal cord compression. While the treatment of mediastinal neuroblastomas in children is total excision if at all possible, this does not mean radical chest wall resection. In the rare case of a massive mediastinal neuroblastoma that cannot be resected without a radical operation, a biopsy to establish the diagnosis is followed by chemotherapy



(a) (b)

Figure 37.8 Left posterior mediastinum neuroblastoma: **(a)** axial view CT scan and **(b)** coronal-view CT scan.

and delayed primary excision. While this clinical situation is unusual, a tissue diagnosis can usually be obtained by a percutaneous core needle biopsy or a thoracoscopic approach avoiding formal thoracotomy. In children with disseminated neuroblastoma, the prognosis continues to be discouraging.

Children with posterior mediastinal neuroblastoma can also present with unusual symptoms. High thoracic and cervical tumors can be associated with Horner syndrome (unilateral ptosis, myosis, anhydrosis). Large thoracic tumors may cause vena cava syndrome. Paraspinal tumors may extend into the neural foramina of the vertebral bodies and cause neurological symptoms.

ANESTHETIC MANAGEMENT OF INFANTS WITH A MEDIASTINAL MASS

Respiratory compromise on induction of general anesthesia in children with large mediastinal masses is a well-recognized complication that must be considered in the preoperative evaluation of any child with a mediastinal mass. Newborns and small children have a small compressible airway, which is associated with significant increased airway resistance with even a modest degree of narrowing. In addition, the mediastinum is not fixed at this age, and large masses can easily displace the mediastinal structures with compression of the tracheobronchial tree, superior vena cava, or right ventricular outflow tract. Cardiac output may also be diminished due to pressure on the great vessels. Induction of anesthesia is associated with a decrease in the functional residual capacity, decrease in lung capacity, and increase in lung retractile force. These alterations are extenuated with the addition of paralysis. Narrowing of the trachea will also occur when the patient changes from spontaneous to positive-pressure ventilation. All of these factors lead to the sometimes critical condition that is associated with general anesthesia in these patients.

The most important factor in preventing anesthetic complications in children with mediastinal mass is a recognition of the aforementioned problems and the anticipation of a possible airway problem. A very thorough radiologic evaluation should be performed, and CT examination to determine the tracheal cross-sectional area maybe of help as well. Once the preoperative evaluation is completed, the anesthetic of choice can be determined depending upon the procedure that will be performed. Preoperative radiation therapy, corticosteroids, or chemotherapy may be required prior to primary excision or biopsy. Incisional biopsies can be performed under local anesthesia in older children, and needle biopsy with local anesthesia can be performed in younger children and infants. In children with benign lesions, one-lung anesthesia with placement of the endotracheal tube beyond the obstruction has been found to be helpful, and occasionally, ventilation through a rigid bronchoscope is necessary. While cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) may be required, these techniques are usually not necessary in the majority of patients. A high index of suspicion, meticulous preoperative evaluation, and a multidisciplinary action plan decided upon by the surgeons, anesthesiologist, radiation therapist, hematology/oncologist, and pathologist can usually advert the potential catastrophe associated with general anesthesia in children with critical mediastinal masses.

OPERATIVE TECHNIQUE FOR REMOVAL OF MEDIASTINAL NEUROBLASTOMA

Resection of posterior mediastinal neuroblastoma has traditionally been approached via a posterolateral thoracotomy. However, in recent years, video-assisted thoracic surgery (VATS) (Figure 37.9) has become more popular among pediatric surgeons, resulting in shorter operative times, less postoperative pain, shorter hospital stay, and excellent cosmetic results. Outcomes for both procedures,

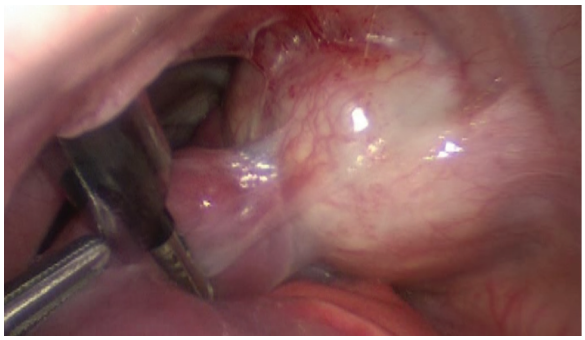


Figure 37.9 Thoracoscopic view of a posterior mediastinum neuroblastoma.

open thoracotomy and VATS, are similar. Surgical resection is facilitated by single-lung ventilation. During VATS, CO_2 insufflation may help to keep the lung out of the surgical field. The lung is retracted medially to reveal the tumor covered with pleura and arising from the sympathetic trunk; an assessment of the lymph node involvement in the tumor vicinity is performed. The pleura is incised around the tumor approximately 1 cm from it and the fascia and pleura mobilized toward the tumor. A plane of dissection can usually be developed superficial to the endothoracic fascia. The tumor is now mobilized from the ribs by sharp dissection, and intercostal vessels entering the tumor will need division. If the tumor extends far enough anteriorly, the azygos vein on the right side will need division. Care is taken to avoid damage to the first thoracic nerve passing laterally across the first rib to join the brachial plexus. The superior intercostal artery normally descends between the first nerve and the sympathetic trunk. Other intercostal nerves may be sacrificed if they are intimate with the tumor.

Depending on how far the tumor has extended anteriorly, it will need to be dissected off the main structures in the superior mediastinum. This is most likely to be the esophagus and the closely applied vagus nerve, but in a large tumor, the trachea may be involved. It may prove useful to have a large size nasogastric tube in the esophagus to aid dissection. On the left side, the thoracic duct and the arch of the aorta with subclavian and carotid branches, along with the vagus, will need protection.

It should now prove possible to dissect the tumor off the bodies of the vertebra, and any extension into the intravertebral foramen should be carefully dissected out. Titanium clips may prove useful to control hemorrhage in small vessels, and these will not interfere with subsequent CT scanning. They may also be used as markers if all tumor is not excised and radiation therapy is being considered. Any suspiciously involved lymph nodes locally should be taken for biopsy (staging).

Congenital airway malformations

ALESSANDRO DE ALARCÓN AND RICHARD G. AZIZKHAN

INTRODUCTION

Congenital airway malformations encompass a broad array of disorders that occur at diverse anatomic levels. The presentation of these disorders varies widely and is influenced by the level at which obstruction occurs as well as the severity of the obstruction. In view of the distinct anatomy of the pediatric airway and the possibility of airway symptoms rapidly progressing to life-threatening airway compromise, early detection, diagnosis, and appropriate management are essential. The aim of this chapter is to present an overview of congenital anomalies extending from the larynx to the distal airway, briefly describing patient assessment, symptomatology, and contemporary management strategies.

ASSESSMENT

Medical history

The evaluation of an infant with respiratory compromise should begin with a thorough review of the infant's history of airway symptoms. Clinicians should explore circumstances that may elicit the onset of symptoms and question parents regarding the duration of symptoms and symptom progression. They should also explore possible swallowing or feeding problems, the nature of the child's cry, and the possibility of foreign-body aspiration. Additionally, any history of endotracheal intubation, trauma, or previous cardiac surgery should be carefully reviewed. All of this information may help to determine the underlying etiology and provide information that significantly impacts management decisions.

Signs and symptoms

Mild airway compromise may manifest with subtle symptoms such as irritability, restlessness, and feeding difficulties. Children with more severe obstruction frequently present with severe suprasternal and intercostal retractions, tachypnea, lethargy, and cyanosis. Stridor, defined as a sound of variable pitch that is produced by turbulent airflow through a partially obstructed laryngeal or tracheal airway, can manifest during either the expiratory or inspiratory phase of respiration or can be biphasic. Inspiratory stridor usually indicates an airway obstruction in the extrathoracic airway, whereas expiratory stridor usually indicates a problem in the intrathoracic airway. Biphasic stridor typically signifies a fixed glottic or subglottic lesion. The pitch of stridor, as well as its relationship to the respiratory cycle, is generally helpful in establishing a differential diagnosis and in establishing priorities for patient assessment. Clinicians should be mindful of the fact that that the degree of stridor does not necessarily reflect the severity of airway obstruction. More specifically, even minimal stridor can reflect the lack of airway movement across a critical airway.

Because stridor is produced by turbulent airflow through the airway, it is not normally seen in children who are intubated or tracheotomy dependent. If seen in a tracheotomized child, it is of particular concern, as it indicates obstruction distal to or within the tracheotomy tube (e.g., mucous plugging) or that the tracheotomy tube is not lying in the trachea.

Diagnostic studies

ENDOSCOPY

In view of the fact that 17% pediatric patients have a synchronous airway lesion, evaluation of the entire airway is imperative. The most critical component of the airway assessment is endoscopy. This may include three endoscopic procedures performed consecutively with the patient under a single anesthesia: (1) flexible bronchoscopy with bronchoalveolar lavage (BAL); (2) microlaryngoscopy and rigid bronchoscopy; and (3) esophagoduodenoscopy with biopsy. Each component of the endoscopic evaluation is aimed at

identifying possible pathology and risk factors that can impact the success of airway reconstruction.

FLEXIBLE BRONCHOSCOPY

Flexible bronchoscopy offers several advantages over rigid bronchoscopy. It can identify particular areas that can cause airway obstruction and that may be missed with a rigid bronchoscope. More specifically, flexible bronchoscopy provides better assessment of disorders such as laryngomalacia, tracheomalacia, and bronchomalacia. Evaluation of the distal airway may provide additional information on vascular compression, bronchiectasis, and assessment of aspiration by BAL.

MICROLARYNGOSCOPY AND RIGID BRONCHOSCOPY

The primary aim of microlaryngoscopy and rigid bronchoscopy is to identify anatomic levels of airway obstruction from the larynx to the carina. The supraglottis is evaluated with attention given to the possibility of supraglottic obstruction such as laryngomalacia and supraglottic stenosis. The vocal fold level is then evaluated for posterior glottic stenosis, anterior glottic web, and laryngeal cleft. If vocal fold immobility is suspected or seen on the fiber-optic endoscopic evaluation of swallowing (FEES) or on voice evaluation, the cricoarytenoid joints should be palpated to determine if there is any fixation of the joint.

Rigid bronchoscopy is performed using a combination of Hopkins rod telescopes and rigid bronchoscopes. The subglottis is initially evaluated. If subglottic stenosis (SGS) is present, it is classified by the Myer–Cotton scale[1] and sized using appropriate endotracheal tubes. Additionally, the length of stenosis and the proximity to the vocal folds is assessed and documented. If a tracheotomy is in place, attention is paid to the evaluation of the suprastomal area, considering the possibility of suprastomal collapse, granuloma, intratracheal skin tract, and high tracheotomy. The trachea is evaluated to the level of the carina, looking for additional pathology, including tracheal stenosis, complete tracheal rings, tracheoesophageal fistula (TEF), TEF pouches, vascular compression, and tracheomalacia.

ESOPHAGODUODENOSCOPY

Evaluation of the upper gastrointestinal tract can provide information that is crucial in decision making as to future surgery. Inflammation in the laryngotracheal complex can be caused by conditions of the upper gastrointestinal tract, resulting in an "active" (i.e., inflamed) larynx. Poor wound healing and scarring are more likely to occur in this setting. The two gastrointestinal conditions associated with laryngeal inflammation are gastroesophageal reflux (GER) and eosinophilic esophagitis (EE). For patients in whom GER is suspected or in whom this condition would have negative consequences on subsequent management, objective evaluation of GER is strongly recommended. The diagnosis of EE is made on esophageal biopsy. Laryngeal inflammation may resolve with appropriate treatment of the underlying condition, permitting surgical reconstruction with a lower risk of complication.

Given that up to 45% of children with congenital airway obstruction also have significant nonairway anomalies, patients also require a thorough overall evaluation. Imaging studies are helpful in diagnosis as well as patient management. Computed tomography (CT) and magnetic resonance (MR) imaging studies provide a rapid and precise way of assessing and measuring the extent and length of airway narrowing or displacement. These investigations are also helpful in detecting associated mediastinal and pulmonary anomalies. Specifically, MR angiography is valuable in assessing the relationship of mediastinal great vessel anomalies (e.g., vascular rings, pulmonary artery slings) to the airway. Newer computer software allows for three-dimensional image reconstruction and is helpful in planning surgical procedures. Echocardiography is valuable in identifying intracardiac defects and most associated great vessel anomalies. Contrast swallow studies are valuable in assessing esophageal motility, aspiration, and some mediastinal lesions that affect the airway. FEES is performed to evaluate structural and functional disorders of swallowing and to identify functional problems of the larynx, pharynx, epiglottis, and proximal esophagus.

CONGENITAL LARYNGEAL ANOMALIES

Laryngomalacia

Laryngomalacia is the most common congenital laryngeal anomaly and is also the most common cause of stridor in neonates.[2] This symptom is usually evident soon after birth or within the first few days of life. It is generally mild but is typically exacerbated by feeding, crying, or lying in a supine position. In 50% of children, stridor worsens during the first 6 months of life. A small subset of children with severe laryngomalacia may present with a spectrum of symptoms, including apnea, cyanosis, severe retractions, and failure to thrive. Also, many patients suffer from clinically significant GER. In extremely severe cases, cor pulmonale is seen. The reported incidence of secondary airway lesions in infants with laryngomalacia varies, with some authors reporting rates as high as 50%[3] and 64%.[4]

Although 50% of children with laryngomalacia experience a worsening of symptoms during the first 6 months of life, laryngomalacia generally resolves by 1 year of age. When the disorder is severe, however, surgical intervention is required.

In most cases, the diagnosis is confirmed by transnasal flexible fiber-optic laryngoscopy. Pathognomonic findings include short aryepiglottic folds, with prolapse of the cuneiform cartilages. Because of the Bernoulli effect, collapse of the supraglottic structures is seen on inspiration, and inflammation indicative of reflux laryngitis is also frequently seen (Figure 38.1). In some patients, a tightly curled (omega-shaped) epiglottis is observed.

The decision as to whether to intervene surgically is based more so on symptom severity than on the endoscopic

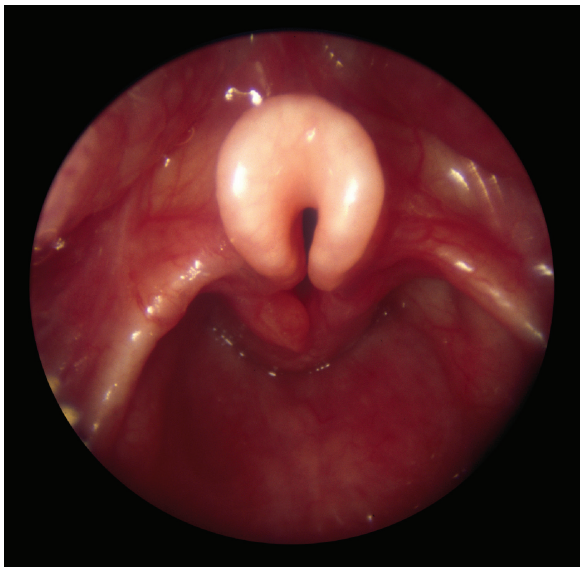

Figure 38.1 Endoscopic view of laryngomalacia in an infant showing partial collapse of the supraglottic structures during inspiration.

appearance of the larynx. For patients with severe symptoms, supraglottoplasty (also termed epiglottoplasty) is the preferred operative procedure, with a reported surgical success as high as 94%.[5–7] Both aryepiglottic folds are divided, and one or both cuneiform cartilages may be removed. If the aryepiglottic folds alone are divided, postoperative intubation is usually not required. Patients should be observed overnight in the intensive care unit. Reflux management with either an H2 antagonist or a proton pump inhibitor is advisable for helping to minimize laryngeal edema. This is especially important in patients with a synchronous airway lesion, as these patients are known to have a higher incidence of GER than those without a synchronous lesion.[3,5] Synchronous airway lesions as well as neurologic conditions and preexisting laryngeal edema can adversely affect operative outcomes.[8] Occasionally, an infant's obstructive symptoms continue despite an adequate postoperative appearance of the larynx. These infants may have an underlying neurologic problem that may become more evident over time. They are therefore far more likely to require tracheotomy placement.

Laryngeal webs

Laryngeal webs result from a failure of recanalization of the glottic airway in the early weeks of embryogenesis. In severe cases, as recanalization commences posteriorly and progresses anteriorly, complete laryngeal atresia may occur. In less severe cases, a thin anterior glottic web may be the only remnant of the recanalization process. The web is typically thickened anteriorly and thins out toward the posterior edge. Associated congenital anomalies are seen in up to 60% of children with webs, and there is a strong association between anterior glottic webs and velocardiofacial syndrome.[9]

Although webs have been described in the supraglottic, glottic, and subglottic regions and may occur anteriorly or posteriorly, anterior glottic webs are the most commonly seen. Some anterior glottic webs are gossamer-thin; however, most are thick and generally associated with a subglottic "sail" that compromises the subglottic lumen. Patients have varying degrees of glottic airway compromise, which usually manifests in an abnormal cry, aphonia, or respiratory distress. Thin webs may elude detection, as neonatal intubation for airway distress may lyse the web, which is curative.

Thick webs require open reconstruction with either reconstruction of the anterior commissure or placement of a laryngeal keel.[10] The presence of thick membranous webs requires placement of a tracheotomy in approximately 40% of patients.

Subglottic stenosis

SGS is an anomaly that involves a narrowing of the subglottic lumen. It can be either congenital or acquired; however, the latter is seen far more frequently and is generally a sequela of prolonged intubation of the neonate. Congenital SGS is thought to be caused by failure of the laryngeal lumen to recanalize during embryogenesis and is one of a continuum of embryologic failures that include laryngeal atresia, stenosis, and webs. It may occur as an isolated anomaly or may be associated with other congenital head and neck lesions and chromosomal anomalies such as a small larynx in a patient with Down syndrome. In the premature infant, SGS is considered present when this lumen measures 3.0 mm or less in diameter at the level of the cricoid, whereas in the full-term neonate, SGS is defined as a lumen of 4.0 mm or less in diameter at this level.

Levels of SGS severity range from mild to severe, and are graded based on the Myer–Cotton grading system (Table 38.1). Patients with mild SGS (no obstruction to 50% obstruction) may present with recurrent upper respiratory infections, often misdiagnosed as croup. In a young child, the greatest obstruction is usually 2 to 3 mm below the true vocal cords.[11] Patients with more severe narrowing (71%–99% obstruction) may present with acute airway compromise and require endotracheal intubation or tracheotomy placement at delivery (Figure 38.2). However, many of these infants, even those

Table 38.1 Myer–Cotton grading system for subglottic stenosis

	Level of airway obstruction	
Classification	From	To
Grade I	No obstruction	50% obstruction
Grade II	51% obstruction	70% obstruction
Grade III	71% obstruction	99% obstruction
Grade IV	No detectable lumen

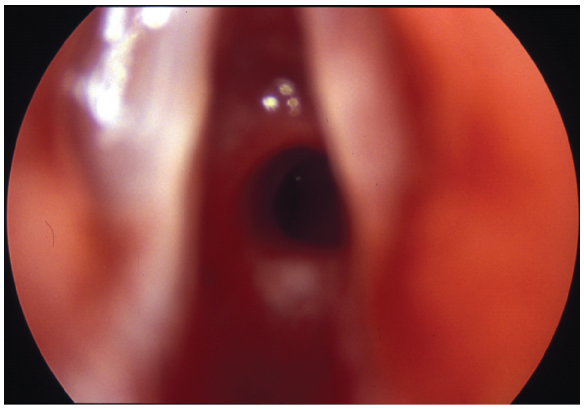

Figure 38.2 Very high-grade subglottic stenosis in a symptomatic neonate.

with grade III SGS (71%–99%), may not be symptomatic for weeks or months. When stridor is present, it initially occurs during the inspiratory phase of respiration. As SGS severity increases, stridor becomes biphasic.

Radiologic evaluation of the nonintubated airway may provide information regarding the site of the stenosis and its extent. Chest x-ray, inspiratory and expiratory lateral soft-tissue neck films, and fluoroscopy are helpful in revealing the dynamics of the trachea and larynx. High-kilovoltage airway films identify the classic steeplelike configuration seen in patients with SGS as well as possible tracheal stenosis, and are therefore of utmost importance. The latter condition is generally caused by complete tracheal rings, which may predispose the patient to a life-threatening situation during rigid endoscopy.

As discussed earlier in this chapter, endoscopic assessment is considered the gold standard. Flexible and rigid endoscopy are used in a complementary fashion for airway evaluation and are both essential. Precise evaluation of the endolarynx should be carried out, including grading of the SGS. Flexible endoscopy provides critical information regarding the structural dynamics of airflow in the hypopharyngeal and laryngeal airways, whereas rigid endoscopy provides an assessment of the entire laryngotracheobronchial airway. Stenosis caused by scarring, granulation tissue, submucosal thickening, or a congenitally abnormal cricoid can be differentiated from SGS with a normal cricoid, but endoscopic measurement with endotracheal tubes or bronchoscopies is required for accurate evaluation.

In children with mild to moderate disease (grade I or II), congenital SGS may improve with age. Children with a minor degree of SGS who experience mild symptoms may nevertheless benefit from endoscopic intervention. Endoscopic options include radial incisions (cold steel or laser) through the stenosis, laryngeal dilatation,[12] and the application of topical or injected steroids. Less than 50% of these patients require tracheotomy placement to maintain their airway. Children with more severe disease are best managed with open airway reconstruction. Laryngotracheal reconstruction using costal cartilage grafts placed through the split lamina of the cricoid cartilage is reliable and has withstood the test of time.[13,14] Costal cartilage grafts can be placed through either the anterior or posterior lamina of the cricoid cartilage or both. These procedures may be performed as a single-stage laryngotracheoplasty[15,16] or as a two-stage procedure, requiring stenting and placement of a temporary tracheostomy.[17] Higher decannulation rates have reportedly been achieved with cricotracheal resection than with laryngotracheal reconstruction in the management of children with severe SGS[18,19]; however, this is a demanding procedure that carries a significant risk of complications. Successful outcomes depend on the management of comorbidities such as GER, EE, and low-grade tracheal infection.

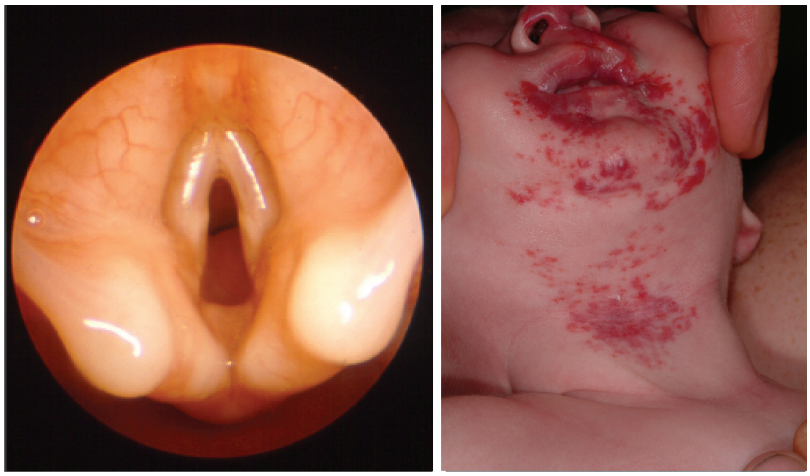
Subglottic hemangioma

Hemangiomas of infancy (also referred to as infantile hemangiomas) are the most common vascular tumors, affecting 1 in 10 white infants in North America[20] and occurring with a threefold female preponderance. These benign lesions usually follow a predetermined phase of growth (proliferation) and later tumor regression (involution). The involutive phase occurs at 12 to 18 months and is generally complete by the first decade of life.

Hemangiomas generally present cutaneously but can occur in any organ or anatomic site. Lesions within the tracheobronchial tree most commonly occur in the subglottis. Their natural history generally mirrors that of cutaneous lesions. More than 50% of children with a subglottic hemangioma also have cutaneous lesions. The latter may therefore provide an indication of the possible presence of a subglottic lesion. The highest-risk (65%) patients are those with a hemangioma occurring in a beard distribution[21] or those with PHACE association, which is characterized by *p*osterior fossa abnormalities, *h*emangiomas of the cervicofacial region that are usually plaque-like and segmental, *a*rterial defects, *c*ardiac and aortic arch defects, and *e*ye abnormalities.[22,23]

As a subglottic hemangioma undergoes proliferation, progressive worsening of the airway usually occurs. Symptoms typically include progressive biphasic stridor with retractions. The degree of obstruction varies and can be exacerbated by certain positions or crying, both of which increase venous pressure and lead to vascular engorgement. When airway narrowing is severe, apnea, cyanosis, and "dying spells" may result.

The diagnosis is based on medical history and findings on rigid bronchoscopy, and although radiologic evaluation (MR imaging with contrast enhancement) is indicated, it rarely reveals extension of the lesion beyond the subglottis. Lesions are typically asymmetric and may be covered by a normal smooth mucosa (Figure 38.3). Because of the risk of hemorrhage, biopsy is not advised. Most patients require treatment, and combining various treatment modalities is often essential.



(a) (b)

Figure 38.3 **(a)** Endoscopic view of a subglottic hemangioma in **(b)** a patient with infantile hemangioma in bearded distribution.

Depending on both the severity of the obstruction and the expertise of involved clinicians, early symptoms are managed with systemic steroids and, more recently, with propranolol—a nonselective beta-blocker. In a landmark article published in the *New England Journal of Medicine* (2008), Leaute-Labreze et al.[24] reported that a child with a large infantile hemangioma who was being treated with propranolol for an unrelated hypertrophic cardiomyopathy exhibited rapid regression of the hemangioma within days of initiating propranolol. These unexpected results spurred numerous investigations and case reports documenting excellent outcomes.[25–30] These outcomes have dramatically changed the paradigm of both pharmacologic and surgical treatment.[31–32]

Vocal cord paralysis

Vocal cord paralysis is the second most common cause of stridor in newborns and may be either congenital or acquired.[33] Congenital vocal cord paralysis generally manifests bilaterally. Although it is usually idiopathic, it is sometimes seen in children with central nervous system pathology (e.g., hydrocephalus and Chiari malformation of the brainstem). Although most children with bilateral paralysis present with significant airway compromise, they have an intelligible voice and do not aspirate.

Acquired disease is generally, though not always, a unilateral condition arising from iatrogenic injury to the recurrent laryngeal nerve. Because of the length and course of the left recurrent nerve, this is far more likely to be damaged than the right recurrent laryngeal nerve. As such, acquired disease usually affects the left vocal cord. Risk factors for acquired paralysis include patent ductus arteriosus repair, the Norwood cardiac repair, and esophageal surgery, particularly TEF repair. In older children, thyroid surgery is an additional risk factor. Unlike children with bilateral vocal cord paralysis, most children with unilateral disease have an acceptable airway but a breathy voice. These children are at a slightly higher risk of aspiration.

The diagnosis of vocal cord paralysis is established with awake flexible transnasal fiber-optic laryngoscopy and/or stroboscopy. Once paralysis has been confirmed, management depends on a number of factors. Children with acquired vocal cord paralysis (whether unilateral or bilateral) may experience spontaneous recovery several months after nerve injury; however, this occurs only if the nerve is stretched or crushed but is otherwise intact.

Children with unilateral paralysis can be initially managed with observation, temporary injection medialization, or speech and voice therapy. Determining the appropriate option is based on a discussion with the patient's family, taking into account the need for restoration of normal voice and improvement of aspiration. Regardless of which option is chosen, these children should be observed for at least 1 year prior to any permanent intervention. If paralysis persists after this period of time and there is a functional deficit, long-term interventions such as ansa cervicalis reinnervation, permanent medialization laryngoplasty, or long-term injection medialization (fat or Radiesse) are considered. These options are discussed with the family and are often influenced by the age of the child and the presence of comorbidities. Medialization laryngoplasty is best performed after puberty.

For patients with bilateral paralysis associated with an underlying disease process, successful treatment of that disease may reverse the paralysis; however, up to 90% of these infants ultimately require tracheotomy placement. Given that up to 50% of children with congenital idiopathic bilateral vocal cord paralysis have spontaneous resolution of their paralysis by 1 year of age,[34] surgical intervention to achieve decannulation is almost always delayed until patients are older than 1 year of age.

Several surgical options have been used for patients with bilateral paralysis, and no particular option offers a

universally acceptable outcome. The aim of surgery is twofold: (1) to achieve an adequate decannulated airway while maintaining voice and (2) to prevent aspiration. Surgical options include laser cordotomy, partial or complete arytenoidectomy (endoscopic or open), vocal process lateralization (open or endoscopically guided), and posterior cricoid cartilage grafting (open or endoscopic).[35–37] In a child with a tracheotomy, it is often prudent to maintain the tracheotomy to ensure an adequate airway prior to decannulation. In a nontracheotomized child, a single-stage surgical procedure can be carried out. Acquired bilateral vocal cord paralysis that does not resolve spontaneously is usually less responsive to treatment than idiopathic cord paralysis. In these cases, more than one operative intervention may be required to achieve decannulation. In patients who have undergone such interventions, postextubation stridor may respond to continuous positive airway pressure (CPAP) or high-flow nasal cannula. The postoperative risk of aspiration should be evaluated by a video swallow study before the child returns to a normal diet. During the initial postoperative weeks, some children have an increased risk of aspirating with certain textures, especially thin fluids.

Posterior laryngeal cleft

Posterior laryngeal cleft is a rare congenital anomaly that results from failure of the laryngotracheal groove to fuse during embryogenesis. This anomaly comprises four anatomic subtypes that differ with respect to involvement of the larynx and/or trachea (Figure 38.4).[38] Patients frequently have coexisting anomalies, many of which affect the airway. Associated airway anomalies include tracheomalacia (almost always present in varying levels of severity), TEF formation (20%), laryngomalacia, vocal cord paralysis, SGS, and innominate artery compression. Associated nonairway conditions include anogenital anomalies, cleft lip and palate, congenital heart defects, and GER, which affects most children. The most common associated syndrome is Opitz–Frias syndrome, which is characterized by hypertelorism, anogenital anomalies, and posterior laryngeal clefting.[39]

Diagnosis can be extremely difficult, as presenting symptoms vary greatly. In type I and type II clefts, symptoms are often subtle and may mimic those of other disorders such as GER. Nonetheless, aspiration is a hallmark clinical feature of this spectrum of disease. With more severe clefts, gross aspiration may occur with associated apnea, cyanosis, and even pneumonia. For milder clefts, the symptoms are those of microaspiration, with choking episodes, transient cyanosis, and recurrent chest infections.[11,39] Airway obstruction manifested by stridor may also be present and is caused by either redundant mucosa on the edge of the cleft or a small cricoid ring. In patients with severe tracheomalacia, especially those with an associated TEF, the airway may be significantly compromised. Contrast swallow studies may demonstrate aspiration; however, rigid laryngoscopy and bronchoscopy are essential for definitive diagnosis. The interarytenoid area is specifically probed to determine if a posterior laryngeal cleft is present.

In children who are symptomatic and do not have other more severe anomalies, repair of the posterior laryngeal cleft should be performed as soon as possible to prevent chronic microaspiration with long-term pulmonary sequelae. Depending on the extent of the airway anomaly, tracheotomy and gastrostomy tube placement may be required before definitive surgical repair of the airway. Because of the high incidence of GER, fundoplication is often required and is preferably performed prior to surgical repair. Most type I and some type II clefts are amenable to endoscopic surgical repair, whereas clefts that extend into the cervical or thoracic trachea often require open repair. A transtracheal approach is advised, as it provides optimal exposure of the cleft while protecting the recurrent laryngeal nerves. A two-layer closure is recommended, with the option of performing an interposition graft if warranted. Type IV long clefts, which extend to the carina or beyond and are often associated with multiple congenital anomalies, are exceedingly difficult to repair and are prone to anastomotic breakdown.[39] Reported success rates for cleft repair vary (50%–90%) depending on both the severity of the cleft and the presence of comorbidities; however, a recent study by de

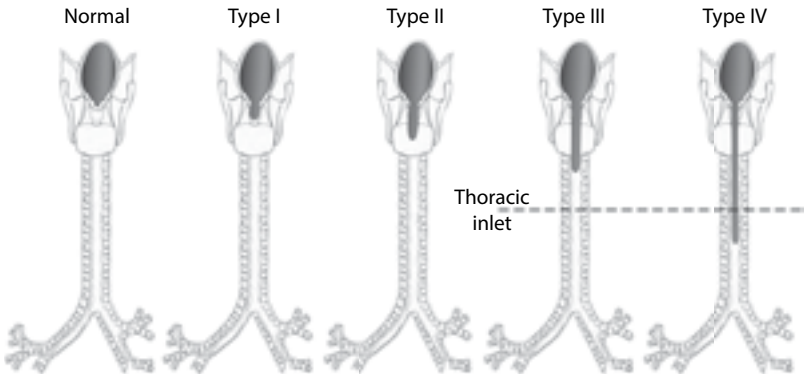


Figure 38.4 Posterior laryngeal cleft classification.

Alarcón et al.[40] reported a high success rate (>90%) despite the presence of additional airway anomalies.

Laryngeal atresia

CONGENITAL HIGH AIRWAY OBSTRUCTION SYNDROME

Congenital high airway obstruction syndrome (CHAOS) is a rare, life-threatening, prenatally diagnosed condition caused by complete or near-complete obstruction of the larynx and trachea. Fetal lung fluid becomes trapped, causing the lungs to become abnormally distended. This creates massive lung expansion that characteristically everts the hemidiaphragms.

This type of fetal airway obstruction may be caused by multiple etiologies, including laryngeal atresia, laryngeal web, tracheal atresia, and laryngeal cyst.[41] Airway atresia is sometimes an isolated anomaly but often is seen in association with genitourinary, vertebral, and cardiac anomalies as well as with hydrocephalus malformation of the aqueduct of Sylvius, bronchotracheal fistula, esophageal atresia, TEF, and syndactyly. Regardless of the etiology, the clinical features and presentation of CHAOS are the same. Prenatal findings on ultrasonography (US) include diffuse and enhanced echogenicity of the lungs, dilated airways, and flattened or everted diaphragms with associated fetal ascites and nonimmune hydrops (Figure 38.5). A fetus identified with these sonographic features is at significant risk of intrauterine death and faces a high likelihood of mortality should the pregnancy progress to delivery. Although US provides a good initial assessment of CHAOS, MR imaging is clearly superior in identifying severity and the level of airway obstruction, and optimizes planning for airway management at delivery.[42] These patients all require delivery by the ex utero intrapartum technique (EXIT) procedure. This procedure maintains placental circulation to the fetus while securing the airway at the time of delivery.[41] Securing the airway may include a full endoscopic diagnostic assessment and tracheostomy.

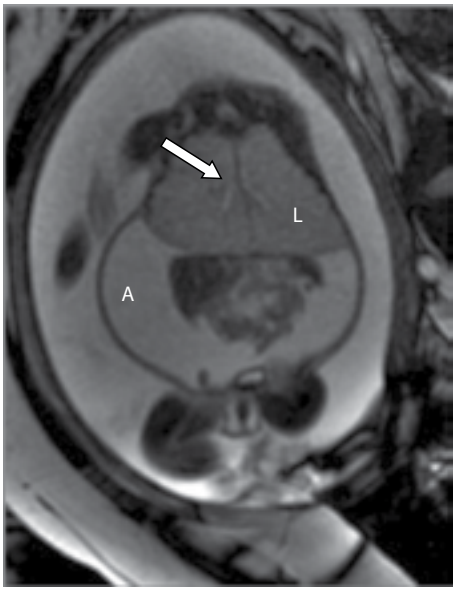

Figure 38.5 Fetal ultrasonography at 27 weeks gestation demonstrating findings consistent with the diagnosis of congenital high airway obstruction: enlarged echogenic lungs (L), dilated airway (white arrow), flattened or everted diaphragms, and fetal ascites (A) and hydrops. (Courtesy of Timothy Crombleholme, MD, Denver, Colorado.)

For the newborn diagnosed with CHAOS, securing and maintaining the airway is the highest priority. These patients are almost always extremely ill and require a prolonged period of critical care and ventilatory support. Once the infant's cardiorespiratory status is stable and other critical or potentially life-threatening anomalies are ruled out, careful endoscopic evaluation of the airway precedes elective laryngotracheal reconstruction; however, consensus has not been reached as to optimal timing of airway reconstruction. Although a functional airway can be constructed, patients do not always attain intelligible speech capabilities.

Diagnosis in the middle of the second trimester generally correlates with a poor perinatal outcome. A fetus presenting in the third trimester with CHAOS in the absence of associated anomalies or hydrops is likely to have incomplete obstruction, and is therefore more likely to survive.

ANOMALIES OF THE TRACHEA AND BRONCHI

Tracheal agenesis and atresia

Tracheal agenesis is a rare developmental anomaly that almost always results in death. Patients who are prenatally diagnosed and in whom the atresia involves only the proximal trachea occasionally survive with the use of an EXIT procedure and eventual tracheal reconstruction. In another form of tracheal agenesis, the entire trachea is absent, and the bronchi come directly off the esophagus. Neonates present at birth with severe respiratory distress, attempting ventilation through bronchoesophageal communications. Temporary ventilation may be possible with esophageal intubation of the esophagus, but this is typically unsustainable. If there is no communication between the airway and the esophagus, CHAOS will result.[41]

Tracheal stenosis and webs

Tracheal stenosis encompasses a broad spectrum of rare tracheal anomalies. Affected segments of the trachea differ in the degree and extent of stenosis, which can range from extremely thin webs to more severe long segments of stenosis affecting the entire airway.

TRACHEAL WEBS

Tracheal webs involve an intraluminal soft-tissue stenosis of the trachea. These webs may be membranous or consist of

thick, relatively rigid tissue. Patients typically present with biphasic stridor or expiratory wheezing, and the severity of these symptoms depends on the degree of the stenosis. Thin webs can be easily managed by hydrostatic balloon dilatation. For thicker webs that are not associated with underlying cartilage deformity, laser ablation is often used.[43] The carbon dioxide (CO_2) or potassium titanyl phosphate (KTP) laser is beneficial for treating lesions in the proximal trachea. Lesions in the distal airway are best managed with the KTP laser, which can be used through small fiber-optic cables. For children with a web greater than 1 cm in length or those in whom the airway cartilage is thought to be structurally deficient or anomalous, operative treatment with segmental tracheal resection or slide tracheoplasty is usually carried out.

CARTILAGINOUS RING APLASIA

Cartilaginous ring aplasia is an extremely rare anomaly in which only a small region of the trachea lacks cartilage, creating a distinct anatomic area that is both malacic and stenotic. The remainder of the trachea is unaffected, and most children do not have coexisting congenital anomalies. Management entails segmental resection of the trachea or slide tracheoplasty,[44] which successfully restores the airway.

TRACHEAL CARTILAGINOUS SLEEVE

Tracheal cartilaginous sleeve is also extremely rare. In children with this anomaly, discrete cartilaginous rings are replaced by a fused cartilaginous cylinder, with or without a membranous portion. It is typically seen in children with craniosynostosis syndromes such as Pfeiffer, Apert, Crouzon, and Goldenhar.[45–47] Neonates usually exhibit respiratory illness. Patients presenting in early infancy often experience acute respiratory symptoms, which may include biphasic stridor with respiratory distress, cough, and frequent respiratory infections. Because of tracheal rigidity, the mechanism for clearing secretions is impaired.

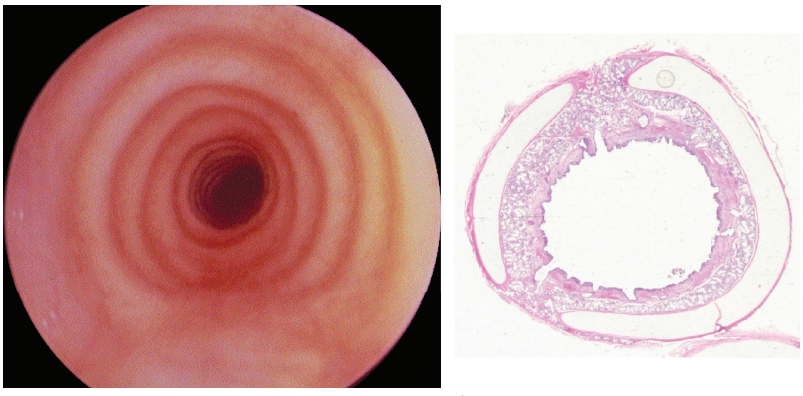
On endoscopy, the anterior tracheal wall appears smooth, though the membranous posterior tracheal wall may be normal, stenotic, or absent. CT and MR imaging are sometimes useful in determining the extent of the lesion. Tracheotomy placement may be used as a temporizing measure. In some cases, observation alone is appropriate. If surgical management is necessary, a slide tracheoplasty is the current gold standard.[48]

COMPLETE TRACHEAL RINGS

Although rare, complete tracheal rings are the most common congenital tracheal stenosis. With this spectrum of potentially life-threatening anomalies, either the trachea alone or both the trachea and bronchi are significantly narrowed. The tracheal cartilage in these patients is abnormally shaped and forms complete rings (Figure 38.6). More than 50% of infants have a segmental stenosis. The clinical manifestations of complete tracheal rings vary from life-threatening respiratory distress during the perinatal period to subtle symptoms of airway compromise in older children. Most symptomatic infants exhibit deterioration of respiratory function over the first few months of life. Symptoms include stridor, retractions, cough, and alterations of cry. Atypical and persistent wheezing and rhonchi and sudden death can also occur. More than 80% of children with complete tracheal rings have other and often multiple congenital anomalies[11]; 50% specifically have congenital heart disease with or without great vessel anomalies.

In some patients, placement of an endotracheal tube may further exacerbate respiratory distress by causing acute swelling and inflammation of the mucosa. Partially obstructing tracheal lesions also may become life threatening following the onset of a respiratory infection. In an infant or child with an abnormal trachea, the cross-sectional area of airway can be significantly decreased with as little as 1 mm of edema. This accounts for the rapid worsening of symptoms in some children with acute inflammatory conditions and coexisting tracheal narrowing.

Prompt diagnostic evaluation to define tracheobronchial anatomy is essential. An initial high-kilovolt airway film may indicate stenosis; however, bronchoscopy is required to reveal the precise location and extent of the stenosis. Bronchoscopy should be performed with extreme caution, using the smallest possible telescopes,



(a) (b)

Figure 38.6 Congenital tracheal stenosis. **(a)** Endoscopic view demonstrating complete tracheal rings. **(b)** Histology showing cartilaginous rings that are circumferential.

and any airway edema in the region of the stenosis may turn a narrow airway into a critical airway.[11] CT scans provide a rapid and precise method of measuring the extent and length of airway narrowing or displacement. Three-dimensional reconstruction of the airway and its relationship to the great vessels aids in operative planning. Furthermore, with new software enhancements, virtual bronchoscopic images can be obtained. These images are particularly useful in assessing the airway distal to the obstruction (Figure 38.7). MR imaging is also valuable in evaluating the relationship of the mediastinal great vessels to the airway. Echocardiography is used mainly to determine whether intracardiac defects are present, and can identify most coexisting pulmonary artery slings.

About 10% of patients with complete tracheal rings are minimally symptomatic and can be managed nonoperatively, though they require ongoing observation.[49] Most children must undergo tracheal reconstruction.[49] Repair of coexisting anomalies such as pulmonary artery sling or vascular ring should be carried out concurrent with the tracheal repair. Although patch tracheoplasty was historically the preferred procedure for long segments of narrowing, slide tracheoplasty is now the procedure of choice for both short- and long-segment stenosis (Figure 38.8).[50] This approach results in significantly less morbidity than other tracheal reconstruction techniques and is adaptable to all anatomic configurations of complete tracheal rings. Slide tracheoplasty uses only autologous tracheal tissue and is performed by transecting the trachea into two equal segments. The anterior wall of the lower half of the trachea and the posterior wall of the upper trachea are incised. These segments are then slid over each other and anastomosed with 5-0 monofilament and absorbable sutures. Postoperatively, the cross-sectional area of the airway has a fourfold increase, and the length of the involved airway decreases by half. Airflow is increased 16-fold.

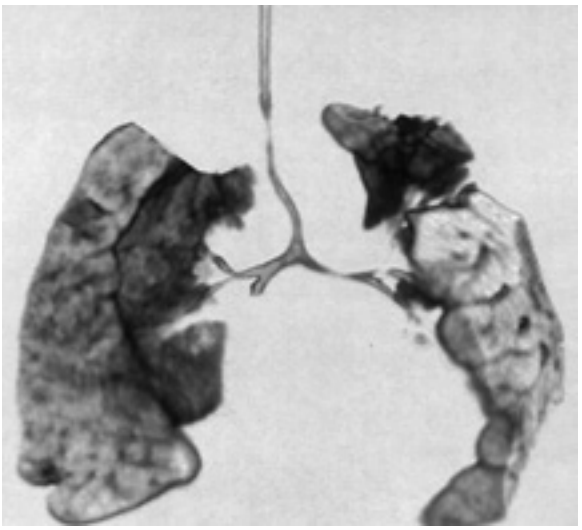


Figure 38.7 Computed tomographic (CT) scan with three-dimensional reconstruction to demonstrate anatomy of the trachea in a patient with congenital tracheal stenosis involving the majority of the tracheal length.

Postoperatively, endotracheal intubation is generally required for 1 to 2 days, though some patients with parenchymal pulmonary disease require longer ventilatory support. During the perioperative period, unnecessary movements of the endotracheal tube or unplanned extubation must be avoided to minimize the risk of damage to the newly reconstructed airway. Nasotracheal intubation is preferred, as the endotracheal tube can be more securely stabilized. Patients require continuous monitoring, careful pulmonary toilet, and endoscopic removal of any obstructing granulation tissue. Immediately prior to extubation, the integrity and patency of the reconstructed airway are assessed by flexible fiber-optic endoscopy through the endotracheal tube, thus ensuring a safe extubation.

Although airway configuration following slide tracheoplasty may resemble a figure eight, this does not indicate airway obstruction. The trachea generally remodels to a normal oval shape within 1 year of reconstruction. In our experience, the long-term survival rate is 90%. Mortality is usually associated with severe comorbidities such as cardiac disease rather than airway complications.

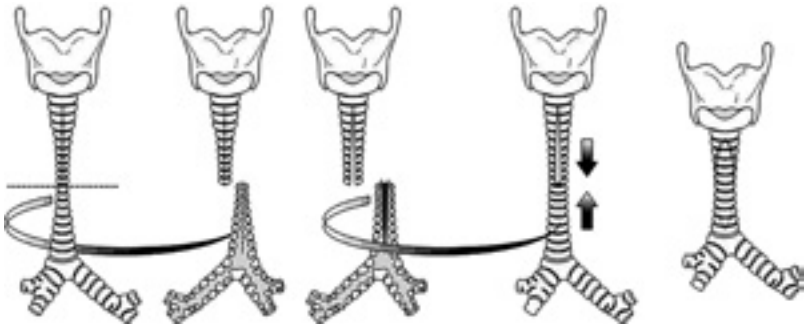

Figure 38.8 Slide tracheoplasty: The trachea is transversely divided at the midpoint of the tracheal stenosis. After proximal and distal tracheal mobilization, the posterior portion of the cephalic trachea segment and the anterior portion of the caudal tracheal segment are incised. The two tracheal segments are then overlapped and obliquely sutured together.

Tracheal diverticulum and tracheal bronchus

Tracheal diverticulum and tracheal bronchus are relatively common embryologic abnormalities of early tracheal budding. Tracheal diverticulum resembles a bronchus, though it originates from the trachea and ends blindly or communicates with a rudimentary lung. Tracheal bronchus most often affects the right-upper-lobe bronchus and may connect to an isolated intrathoracic lung segment or the apical segment of an upper lobe. Both anomalies frequently occur along with other tracheal, esophageal, and pulmonary anomalies. Diagnosis is established by airway endoscopy. Most children are asymptomatic and do not require treatment. Pneumonia and respiratory distress may be the presenting symptoms during the neonatal period. These symptoms are almost always associated with stenosis of a bronchus or other lung anomalies. Resection of involved lobe and bronchus in these patients is generally curative.

The most common cause of tracheal diverticulum is iatrogenic, following division of a TEF where a small remnant of the esophagus is left on the tracheal side. These defects can be readily managed with endoscopic resection.[51–53]

Airway malacia

Airway malacia is a condition in which the structural integrity of either the trachea or bronchi or both are weakened, and the cartilaginous rings of the airway lack the rigidity required to avoid airway collapse during expiration. Malacia may be localized or occur diffusely throughout the airway. Tracheomalacia is the most common congenital tracheal anomaly. This condition may occur in isolation or in conjunction with other congenital anomalies. TEF, esophageal atresia, and posterior laryngeal clefts are particularly common associations.[54] Premature neonates and children with chronic lung disease are at high risk for developing combined severe tracheobronchomalacia.

Presenting symptoms vary depending upon the severity, duration, and region of airway involvement. Most children are either asymptomatic or minimally symptomatic, and most cases involve posterior malacia of the trachealis, with associated broadening of the tracheal rings. Presenting symptoms may include a honking cough, stridor, wheezing, respiratory distress when agitated, and cyanosis. Some children are misdiagnosed with allergic asthma and unsuccessfully treated with bronchodilators. Diagnosis is best established by bronchoscopy, with the patient breathing spontaneously; this demonstrates dynamic distortion and compression of the trachea. In children who are minimally symptomatic, symptoms often resolve by age 3. These children are managed with observation alone. Children who experience symptom progression require medical or surgical intervention.[54] For some patients, respiratory monitoring with nasal CPAP may be sufficient to effect improvement.

Segmental tracheal involvement is managed with endoscopic or open aortopexy, with thymectomy and anterior suspension of the ascending arch of the aorta to the posterior periosteum of the sternum.[55] More diffuse malacia may require tracheotomy placement with positive-pressure ventilation over a long duration. For patients with severely problematic tracheobronchomalacia that is unresponsive to nonoperative therapy or unsuitable for surgical treatment, intratracheal stents are placed. This approach is, however, associated with serious complications, such as stent collapse, stent dislodgement, or rarely, stent erosion into the great vessels. Additionally, stent removal can cause tracheal tearing or major hemorrhage.

Esophageal bronchus

Isolated bronchial connection between the esophagus and the airway is extremely rare and occurs more frequently in females (2:1). Associated cardiac, genitourinary, vertebral, and diaphragmatic anomalies are common. Esophageal bronchus is thought to develop from a supernumerary lung bud arising from the esophagus. Most commonly, a lower lobe is aerated by this ectopic bronchus; however, an entire main bronchus and lung may be affected. As in pulmonary sequestration anomalies, the pulmonary vasculature may be abnormal, with the arterial supply coming off the aorta and venous drainage going into either the systemic or pulmonary veins.

Inadequate bronchial drainage usually results in recurrent pulmonary infection and parenchymal damage.[56] Nonetheless, some patients remain undiagnosed until adolescence or adulthood despite recurring pneumonias and persistent radiographic abnormalities. Although radiographic findings vary with the segment of the lung affected by the anomaly, collapse, consolidation, cavitation, and cyst formation within the pulmonary parenchyma are commonly seen. The diagnosis is confirmed by a contrast study of the esophagus, though false-negative results sometimes occur. Excision of the abnormal lung and closure of the bronchoesophageal fistula is the treatment of choice in patients beyond the neonatal period. Prognosis depends on early diagnosis and treatment and the severity of associated anomalies. Bronchotracheal reconstruction has been successfully accomplished in neonates diagnosed with esophageal bronchus.[57]

Tracheobronchial–biliary fistula

A congenital tracheobronchial–biliary fistula is an anomalous tract that connects the respiratory tree with the biliary tree. This is an extremely rare developmental anomaly that is thought to arise from the distal trachea or either mainstem bronchus. To date, only 25 cases have been reported in the English-language literature.[58] An association with other foregut anomalies also has been reported.[59] Children usually present with recurrent pneumonias, respiratory distress, and failure to thrive, often starting early in the neonatal period; however, the cardinal symptom is bile-stained sputum. Symptom severity varies and primarily depends on

whether the bile from the left lobe of the liver has normal drainage channels to the duodenum or only drains through the bronchobiliary fistula.[59–61] The diagnosis is established by either bronchoscopy or endoscopic retrograde cholangiopancreatography (ERCP); however, a case report reported in 2008[58] offered optimism for using contrast-enhanced CT of the chest and abdomen as a method of diagnosis. Surgical interruption of the fistulous tract is the only effective therapy for this malformation.

Bronchogenic cyst

Bronchogenic cysts stem from aberrant embryogenesis of the bronchial tree in which a segment of the lung bud develops independently. The walls of the cyst often contain fibrous tissue and cartilaginous remnants, while the internal surface consists of ciliated columnar epithelium.[62] Lesions usually expand, causing extramural compression of the airway. The most commonly seen symptom in infants is respiratory distress. Coughing, wheezing, or chest pain also may be present. A plain chest radiograph may suggest the presence of a bronchogenic cyst. A CT scan or MR imaging is valuable in establishing a definitive diagnosis (Figure 38.9a). Patients are successfully managed by open or thoracoscopic resection (Figure 38.9b).[63–64]

Bronchial atresia and bronchial lobar agenesis

BRONCHIAL ATRESIA

Localized bronchial atresia is a rare abnormality in which the atretic bronchus impedes the flow of secretions and air from the distal lung to the main tracheobronchial tree. This condition may mimic lobar emphysema or a mediastinal mass.[65] At birth, the affected lung retains fluid. Eventually, however, the anomalous lobe or segment becomes hyperaerated as air enters through the pores of Kohn. Secretions accumulate proximal to the atresia, resulting in the formation of a mucocele.[66] Emphysema of the segment may cause atelectasis of the normal lung tissue, which may be manifested by wheezing and stridor. Plain chest films may reveal a hilar mass with radiating solid channels surrounded by hyperinflated lung. A CT chest scan may show a cystic central mucocele and is valuable in distinguishing bronchial atresia from a bronchogenic cyst or lobar emphysema. Although children may initially be asymptomatic, secretions trapped in the lung may result in serious pulmonary infection. Surgical resection of the affected lobe restores normal lung function.

BRONCHIAL LOBAR AGENESIS

Bronchial agenesis is more commonly seen than tracheal agenesis, and unlike tracheal agenesis, it is compatible with life. Several anatomic forms have been described; these include lobar, bronchial, and parenchymal agenesis. In the most severe form, complete agenesis of the lung and its bronchus and blood supply may occur.[65] Also, there may be a rudimentary bronchus and aplasia of the lung. As with most airway malformations, children may have coexistent congenital anomalies; most commonly, these anomalies involve the skeletal, cardiovascular, gastrointestinal, and genitourinary systems. Diagnosis is established by chest radiographs and airway endoscopy. Most patients can be managed nonoperatively. These abnormalities are important to identify in that they may mimic other airway anomalies requiring treatment (e.g., bronchial stenosis or extraluminal airway obstruction by tumors or masses).

Bronchial stenosis

Isolated congenital bronchial stenosis is extremely rare, with causality including compressive vascular, cardiac, and congenital cystic lesions or soft-tissue cartilaginous stenoses. Symptoms and treatment vary, depending on both the severity and anatomic location of the lesion. Surgical management includes resection and reconstruction of the bronchus and slide bronchoplasty.[67,68] Acquired bronchial

stenosis is more common than its congenital manifestation, and is a significant cause of morbidity and mortality in infants who have undergone prolonged intubation and respiratory support. Most such cases can be managed with endoscopic balloon dilatation or laser resection.

Vascular rings

BENJAMIN O. BIERBACH, JOHN MARK REDMOND, AND CHRISTOPHER HART

INTRODUCTION

Vascular rings are unusual congenital anomalies that occur early in the development of the aortic arch and great vessels. The primary symptoms associated with vascular rings relate to the structures that are encircled by the ring, namely, the trachea and esophagus.

DEFINITION AND HISTORY

A vascular ring is a rare congenital condition in which an anomalous configuration of the aortic arch or associated vessels surrounds the trachea and esophagus, to form a complete compressing ring around them. Several other related vascular anomalies involving aortic arch vessels do not form complete rings but have been grouped descriptively with vascular rings because they can produce similar symptoms related to compression of the trachea and or esophagus. In common usage, however, the definition of a complete vascular ring is extended to include pulmonary artery slings, which do not completely surround the trachea and esophagus but may compress them. Both complete and incomplete rings and slings are discussed in this chapter.

The first vascular ring described was that of a double aortic arch by Hommel[1] in 1737. Subsequently, Bayford reported a retroesophageal right subclavian artery in 1794 after performing an autopsy on a woman who had experienced dysphagia for years and died of starvation. Maude Abbott described five cases of double aortic arch in 1932 and made the suggestion that surgical intervention should be undertaken in such cases.

The term *vascular ring* was first used by Dr. Robert Gross[2] in his report describing the first successful division of a double aortic arch.

Potts and Holinger coined the term *pulmonary artery sling* when they reported the first successful repair of this anomaly in a 5-month old with wheezing and intermittent episodes of dyspnea and cyanosis.[3] This anomaly was, however, first reported in a postmortem study in a 7-month-old infant with severe respiratory distress.[4]

Although innominate artery compression syndrome and pulmonary artery sling are not complete anatomic rings, they have been traditionally classified with classic vascular rings because of the similarities in patient presentation, diagnosis, and surgical therapy.

FREQUENCY

Vascular rings are uncommon anomalies and make up less than 1% of all congenital cardiac defects. They occur with about equal frequency in both sexes. No geographical or racial predominance exists. Some vascular rings are associated with other congenital heart defects, while others may be isolated malformations.

The two most common types of complete vascular rings are double aortic arch and right aortic arch with left ligamentum arteriosum. These make up 85%–95% of cases. Two other complete vascular rings that are extremely rare (<1%) include right aortic arch with mirror-image branching and left ligamentum arteriosum, and left aortic arch with retroesophageal right subclavian artery, right-sided descending aorta, and right ligamentum arteriosum.

Other anomalies that produce symptoms but do not form a complete anatomic vascular ring make up the remainder and include the anomalous innominate artery and the anomalous right subclavian artery with left-sided aortic arch and left ligamentum arteriosum.

The anomalous left pulmonary artery or pulmonary artery sling makes up about 10% of cases, and, although it is not associated with anomalies of the aortic arch or its branches, it arises from an abnormality of the sixth branchial arch and produces a complete ring. This anomaly is associated with intracardiac defects in 10%–15% of cases.

EMBRYOLOGY

In 1922, Congdon[5] reported his extensive experience with the study of the embryogenic development of the human

aortic arch system. Edwards[6] developed a schematic model with a double aortic arch system and bilateral ductus arteriosus (Figure 39.1).

Vascular rings are a group of congenital anomalies caused by different regressions and involutions from the embryonic aortic arch system. Several recent papers report the close association of band 22q11 deletion with anomalies of the aortic arch as well as other congenital cardiac abnormalities. In the embryonic aortic arch system, the ventral and dorsal aortae are connected by six primitive aortic arches. The embryo then utilizes the mechanism of programmed cell death (apoptosis) to eliminate redundant and unnecessary components. The multiple branchial arches in the human embryo are an excellent example. They represent the blood supply of gill-breathing organisms, which lie in our phylogenetic past. They are transiently present during human development but either partially or completely disappear as the pulmonary circulation develops and connects with the heart. Only a few segments usually remain. In case unnecessary segments persist, anomalies such as vascular rings may result.

The paired right and left dorsal aortae, one of which will eventually become the descending thoracic aorta, are present in the embryo by approximately the 21st day of intrauterine life. Subsequently, the first to sixth branchial arteries form bilaterally, each with its own aortic arch communicating from the aortic sac to the dorsal aortas.

At this point in development, multiple vascular rings are present. The first and second arches largely resorb and contribute only to minor facial arteries, while the third arches form the carotid arteries. The left fourth arch forms the distal aortic arch and aortic isthmus from the origin of the left common carotid artery to the origin of the descending thoracic aorta, which itself represents a persistence of the left dorsal aorta. So, if the right fourth arch involutes, a normal left arch is formed, which results in the aorta passing from the anterior to the posterior mediastinum to the left of the trachea and esophagus. If the left fourth arch involutes, a right aortic arch is formed. In this case, the aorta courses to the right of the trachea and esophagus from the anterior to the posterior mediastinum.

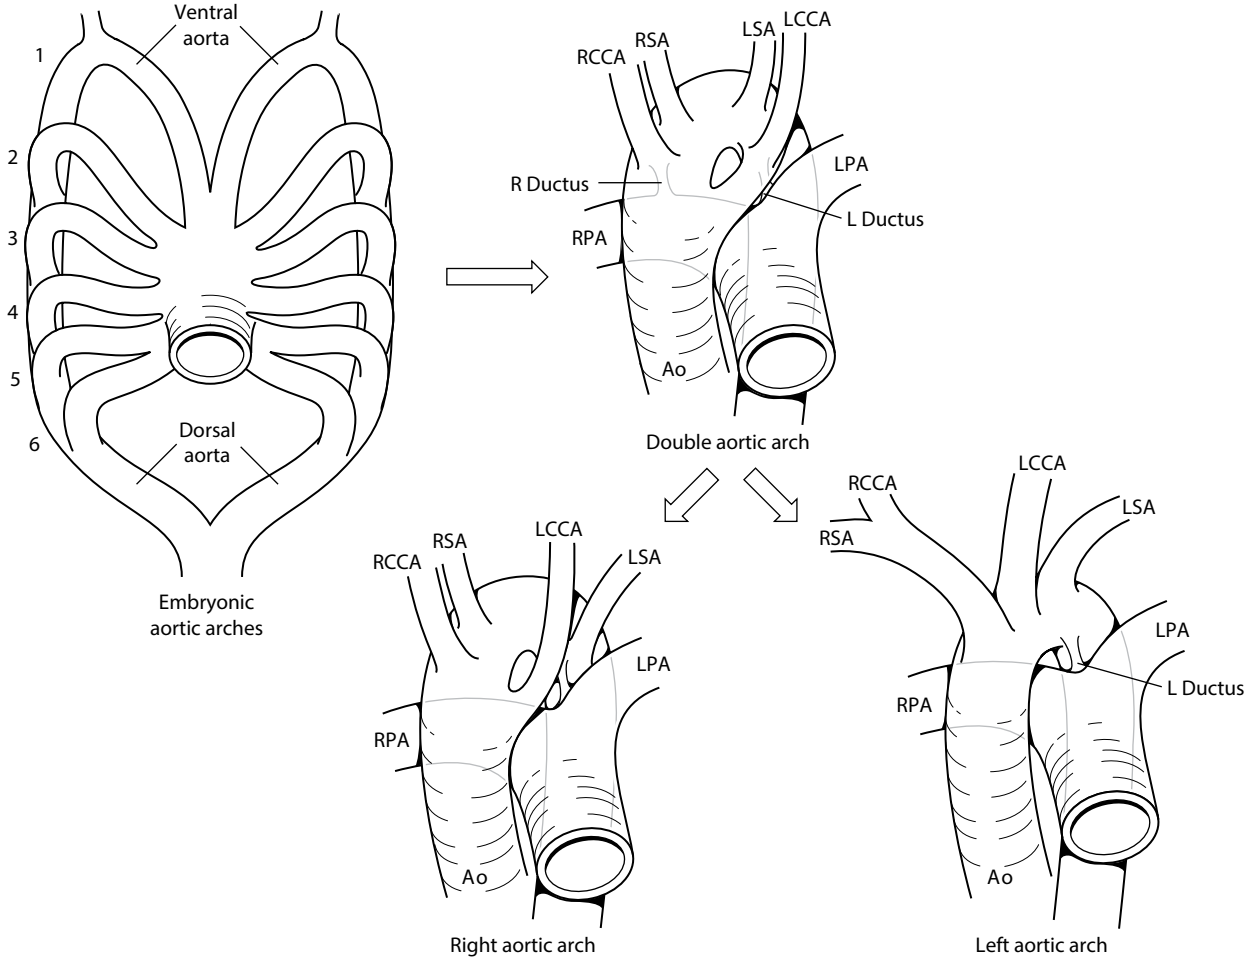

Figure 39.1 Diagram of the embryonic aortic arches. Six pairs of aortic arches originally develop between the dorsal and ventral aorta. The first, second, and fifth arches regress completely. Preservation or deletion of different segments of the rudimentary arches results in a double aortic arch, a right aortic arch, or the normal left aortic arch. Ao: aorta; LCCA, RCCA: left and right common carotid artery; LPA, RPA: left and right pulmonary artery; LSA, RSA: left and right subclavian artery.

Proximally, septation of the conotruncus produces the ascending aorta, which joins with the fourth left arch. The right dorsal aorta ultimately contributes to the right subclavian artery. The first, second, and fifth arches involute to form the Edwards classic double aortic arch.

Stewart et al.[7] summarized these pathologic, embryologic, and roentgenographic correlations of the lesions contributing to anomalies of the aortic arch.

FORMS

Different variations of vascular anomalies exist (listed by incidence):

1. Double aortic arch
2. Right aortic arch
3. Pulmonary artery sling
4. Vascular rings associated with left aortic arch
5. Cervical aorta

Double aortic arch

Double aortic arch is an anomaly in which both right and left arches are present and may be one of several variations (Figure 39.2a–c):

a. Both arches widely patent
b. Hypoplasia of one arch (usually the left)
c. Atresia of one arch (usually the left).

Double aortic arch represents a persistence of both right and left embryonic fourth branchial arches joining the aortic portion of the truncoaortic sac to their respective dorsal aorta. The ascending aorta bifurcates anterior to the trachea, and each arch courses either to the left or to the right of the trachea or esophagus. The larger of the two arches usually crosses posterior to the esophagus and joins with the other arch in the posterior mediastinum to form the unified descending aorta. Thus, a complete vascular ring is formed. Note that the right recurrent laryngeal nerve has to pass around the right aortic arch, rather than being in its usual position around the right subclavian artery. Double aortic arch is rarely associated with congenital heart disease, but when present, tetralogy of Fallot and transposition of the great vessels are most common.

Right aortic arch

In cases of individuals in whom the left fourth branchial arch involutes and the right remains, a right aortic arch is present (Figure 39.3a–c). Right aortic arch occurs less frequently than 1 in 100,000 times in the general population and may exist in the absence of any other anomalies. Its presence is suggestive of the existence of an associated anomaly. About 30% of patients with tetralogy of Fallot have an associated right aortic arch. Persistence of the right arch with involution of the left creates a situation in which the origins of the left subclavian artery and ductus arteriosus can vary. Several of these configurations can produce a vascular ring.

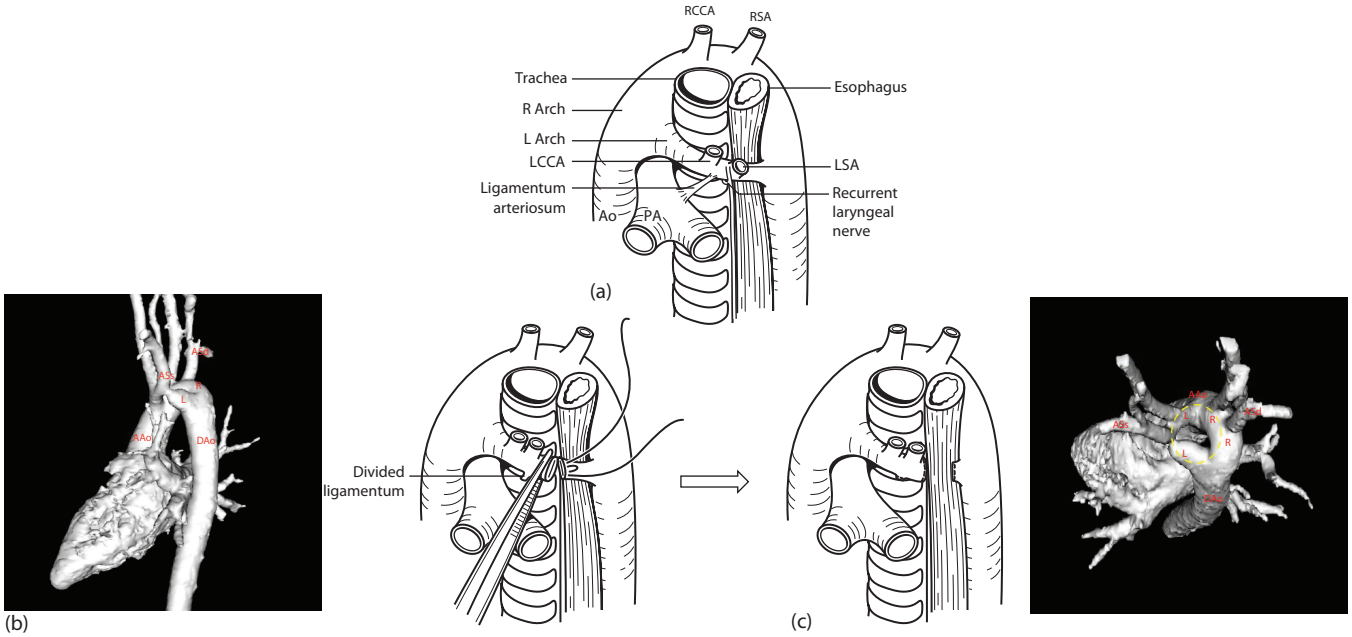

Figure 39.2 Division of a double aortic arch **(a)**. Double aortic arch with a dominant right aortic arch. The lesser left aortic arch is divided between two applied vascular clamps. The stumps are oversewn, and this opens up the desired space for the trachea and esophagus. Ao: aorta; LCCA, RCCA: left and right common carotid artery; PA: pulmonary artery; LSA, RSA: left and right subclavian artery. 3-D rendered images from a contrast-enhanced MRI of a 4-year-old boy with tracheal compression by a double aortic arch. In **(b)**, a left lateral view, and in **(c)**, a cranial view is provided. Interrupted circle: ring formation from both arches; AAo: ascending aorta; DAo: descending aorta; R: right aortic arch; L: left aortic arch; ACs: left carotid artery; ACd: right carotid artery; ASs: left subclavian artery; ASd: right subclavian artery.

Ao: aorta; LCCA, RCCA: left and right common carotid artery; MPA: main pulmonary artery; LSA, RSA: left and right subclavian artery. 3-D rendered images from contrast-enhanced MRI of a 2½-year-old boy with tracheal compression by a right aortic arch and abnormal left subclavian artery originating from a large diverticulum of Kommerell. In **(b)**, an anterior view, and in **(c)**, a left lateral view is provided. Arrow: compression of trachea; Tr: trachea; AAo: ascending aorta; DAo: descending aorta; R: right aortic arch, ACs: left carotid artery; ASs: left subclavian artery; K: diverticulum of Kommerell; RV: right ventricle; PA: pulmonary artery; LPA: left pulmonary artery.

RIGHT AORTIC ARCH WITH ABERRANT LEFT SUBCLAVIAN ARTERY AND LEFT LIGAMENTUM ARTERIOSUM

In this anomaly, the right arch first gives off the left carotid artery, which travels anterior to the trachea. It then gives off the right carotid, followed by the right subclavian artery, and, lastly, the left subclavian artery, which courses in a retroesophageal position and gives rise to the ligamentum arteriosum from its base. The ligamentum arteriosum connects the left subclavian or descending aorta to the left pulmonary artery. The trachea and esophagus are surrounded by the ascending aorta anteriorly, the aortic arch on the right, the descending aorta posteriorly, and the ligamentum arteriosum and left pulmonary artery on the left (Figure 39.3b and c). Almost 10% of these defects are associated with an intracardiac defect.

RIGHT AORTIC ARCH WITH MIRROR-IMAGE BRANCHING AND RETROESOPHAGEAL LIGAMENTUM ARTERIOSUM

In these cases, only partial resorption of the distal left fourth arch occurs. The first brachiocephalic vessel originating from the right arch is the left innominate artery, which, in turn, branches into a left carotid and left subclavian artery. These vessels course anterior to the trachea. Following these, a right carotid artery and then a right subclavian artery arise. The ligamentum arteriosum is the final structure arising from the arch in this sequence. It originates from an area called the Kommerell diverticulum, which represents the nonresorbed remnant of the left fourth arch and is situated at the point of merger between the right arch and the proximal descending thoracic aorta. The ligamentum passes leftward and behind the esophagus and then travels anteriorly to join with the left pulmonary artery and complete the ring.

More commonly, in cases of right aortic arch with mirror-image branching, the ligamentum arteriosum travels from the mirror-image innominate or left subclavian artery to the left pulmonary artery. A complete ring is not present in these cases. Most importantly, this type of vascular ring has a more than 90% association with intracardiac defects.

Pulmonary artery sling

Typically, the left pulmonary artery arises directly from the right pulmonary artery and passes leftward between the trachea and the esophagus (Figure 39.4).[8] The ligamentum arteriosum passes posteriorly from the origin of the right

MPA, LPA, RPA: main pulmonary artery, left pulmonary artery, and right pulmonary artery; inset: lateral view of anterior compression of the esophagus. 3-D rendered images from contrast-enhanced MRI of a 2-week-old male newborn with severe tracheal/bronchial compression and air trapping by a pulmonary sling. In **(b)**, a posterior view of all vascular structures, and in **(c)**, a posterior view only on the pulmonary arteries is provided. Arrow: compression of trachea and right bronchus; Tr: trachea (airways); LB: left bronchus; RB: right bronchus; DAo: descending aorta; RV: right ventricle; PA: pulmonary artery; LPA: left pulmonary artery; RPA: right pulmonary artery.

pulmonary artery, where it arises from the main pulmonary artery to the undersurface of the aortic arch, thus creating a vascular ring surrounding the trachea but not the esophagus. The left pulmonary artery is often relatively hypoplastic. In contrast, the right pulmonary artery appears larger than normal and almost like a direct extension of the main pulmonary artery. The small calibre of the left pulmonary artery may explain the high incidence of anastomotic problems that have been observed in the past with attempts to reimplant the vessel at the main pulmonary artery.

This lesion is often associated with hypoplasia and other abnormalities of the tracheal and bronchial cartilages. Most patients are symptomatic by 1 month after birth. Respiratory symptoms predominate, as the most severe compression is on the trachea. More than 50% of infants also have severe tracheobronchial anomalies such as absence of the posterior membranous component, tracheomalacia, stenosis, webs, or complete tracheal rings. Although the presence of complete rings does not imply that high-graded stenosis will be observed, the trachea is often narrower than normal. The complete rings may be localized at the region where the sling passes around the trachea, although in some cases, the entire trachea consists of complete ringed cartilages. Severe stenosis can involve the carina and extend for a considerable distance into one or both mainstem bronchi. Intracardiac defects are also seen in 20% of these infants.

Vascular rings associated with left aortic arch

Two extremely rare complete rings occur in the presence of a left aortic arch, and both are associated with a right-sided descending thoracic aorta.

LEFT AORTIC ARCH WITH RIGHT DESCENDING AORTA AND RIGHT LIGAMENTUM ARTERIOSUM

The first arch vessel to exit the left aortic arch is the right common carotid, which passes anterior to the trachea. The left carotid is next, followed by the left subclavian artery. The right subclavian artery arises more distally as a branch of the proximal right-sided descending aorta. The ligamentum arteriosum arises from the base of the right subclavian artery or a nearby diverticulum and travels to the right pulmonary artery.

LEFT AORTIC ARCH, RIGHT DESCENDING AORTA, AND ATRETIC RIGHT AORTIC ARCH

The brachiocephalic vessels arise from the left-sided arch in a normal arrangement. The left arch passes behind the esophagus to join a right-sided descending aorta. An atretic right arch is present and completes the ring.

LEFT AORTIC ARCH AND LEFT LIGAMENTUM ARTERIOSUM WITH RETROESOPHAGEAL RIGHT SUBCLAVIAN ARTERY

This is the most common of the arch vessel anomalies, occurring in about 0.5% of the population (Figure 39.5). In these cases, the right subclavian artery does not arise from an innominate trunk with the right carotid artery but originates as the last brachiocephalic branch from the descending aorta and takes a retroesophageal route to its destination (Figure 39.5). In this case, the right subclavian artery is called *arteria lusoria*. A normally positioned ligamentum arteriosum is present on the left. If a right ligamentum arteriosum were present instead of one on the left, its course would proceed from the base of this anomalous right subclavian artery to the right pulmonary artery, and a complete ring would exist. Instead, no true vascular ring is present in these cases. Most patients are symptomatic, but the occasional patient may present with dysphagia.

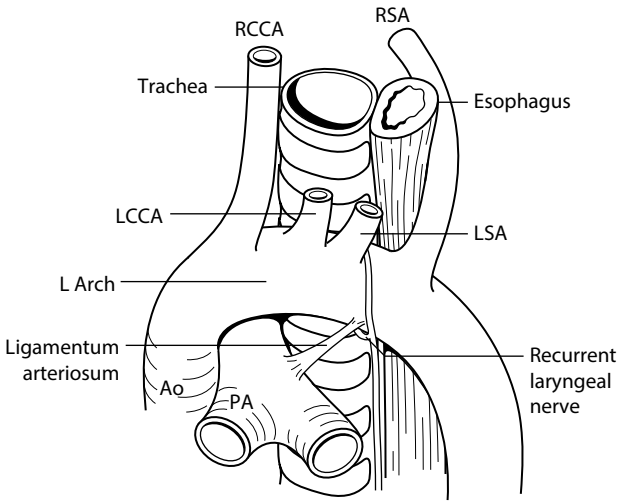

Figure 39.5 Left aortic arch with aberrant right subclavian artery compressing the esophagus. Ao: aorta; LCCA, RCCA: left and right common carotid artery; PA: pulmonary artery; LSA, RSA: left and right subclavian artery.

LEFT AORTIC ARCH WITH ANOMALOUS ORIGIN OF THE INNOMINATE ARTERY

The actual prevalence of this abnormality is widely debated (Figure 39.6). This is because in as many as 90% of cases in which symptomatic tracheal compression is produced by the innominate artery, the vessel is noted angiographically to have a normal origin from the aorta. When an anatomic abnormality is noted in these cases, the innominate artery appears to originate from a more distal and leftward position on the arch than normal. As it takes its course from left to right, it crosses the trachea anteriorly and in doing so may produce compression of the trachea.

Cervical aorta

This a rare anomaly in which the aorta ascends into the neck on the right or left side, forming a pulsatile mass in the supraclavicular region. Several morphological types have been described according to the side of the aortic arch (contralateral or ipsilateral) and the origin of the head and neck vessels.[9]

CLINICAL FINDINGS

Clinical manifestations are related to the nature of malformation and tightness of the ring. Most children with

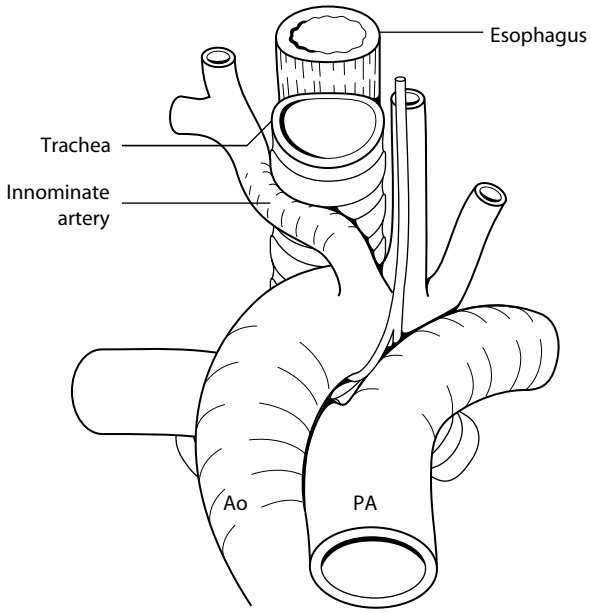

Figure 39.6 Innominate artery compression of the anterior trachea. Ao: aorta; PA: pulmonary artery.

vascular rings present with symptoms in the first few months of life and require surgery within the first year of life.[10] The classic sign of a child with a vascular ring is the "seal-bark" cough. In addition, noisy breathing may be heard during both inspiration and expiration (biphasic stridor), while in asthma, the noise is mainly at the end of expiration. A common finding in all forms of vascular rings is fact that recurrent respiratory infections occur.

In children with double aortic arches, if both arches are widely patent, the rings are tight, and patients present with biphasic stridor in the first weeks of life. In case one arch is hypoplastic or atretic, the rings are usually looser, with presentation at 3–6 months of age. Rarely does a double aortic arch present in adulthood. Children with double aortic arches are often small and poorly developed, and hold their head in hyperextension. Repeated severe respiratory infections may occur.

Children with a pulmonary artery sling and/or complete tracheal rings often have severe respiratory distress requiring emergent intubation and ventilation.

Children with the innominate artery compression syndrome often present with apnea as an initial symptom.

Feeding difficulties occur when solid feeding is attempted to be introduced to the infant. This results in dysphagia and only tends to occur in older children. Gastroesophageal reflux with concomitant pain or fear of food intake is observed. Cyanotic spells in these young patients may have caused episodes that are termed apparent life-threatening events (ALTE) or death spells, in which acute apneic or severe obstructive events are accompanied by cyanosis.

Physical exam may be within normal limits, but one may see coughing, dyspnea, drooling, or dysphagia. Infants will feed poorly due to respiratory distress and may have life-threatening episodes of apnea and cyanosis.

Cardiac exam will most often be normal. Lung exam may or may not show evidence of pneumonia.

ASSOCIATED SYNDROMES AND NONCARDIAC CONDITIONS

Double aortic arch is associated with a chromosome band 22q11 deletion in approximately 20% of patients. Band 22q11 deletion is responsible for *DiGeorge*, *velocardiofacial*, and conotruncal anomaly face syndromes, which are often referred to using the unified terms CATCH-22 syndrome and chromosome band 22q11 deletion syndrome. In patients with double aortic arch, the frequency of phenotypes satisfying the clinical criteria for these various syndromes is not known. Rather, the important point is that double aortic arch may be associated with band 22q11 deletion, which has various other possible manifestations. These include, but are not limited to, palatal abnormalities, laryngotracheal anomalies, speech and learning delay, characteristic facial features, *hypocalcemia*, abnormalities of T-cell-mediated immune function, and neurologic defects.

Occasionally, patients with double aortic arch may have anomalies consistent with either vertebral, anal, cardiac, tracheal, esophageal, renal, and limb (VACTERL) or posterior coloboma, heart defect, choanal atresia, retardation, genital, and ear (CHARGE) associations. Double aortic arch has also been reported in association with other chromosomal anomalies, such as trisomy 21 and other syndromes.

One of the more important noncardiac features that sometimes are found in association with double aortic arch is esophageal atresia, insofar as an undiagnosed arch anomaly may complicate repair of the esophageal atresia, which is usually recognized earlier than the double aortic arch.

Another noncardiac anomaly that may be associated with vascular rings is a congenital laryngeal web, which may present with the same symptoms and signs as a vascular ring. Accordingly, patients with persistent stridor or upper airway obstruction after repair of a vascular ring, particularly those with a chromosome 22q11 deletion, should be evaluated for the presence of a congenital laryngeal web.

DIAGNOSTIC TESTS

Laboratory studies

No laboratory screening or diagnostic study exists for this abnormality.

Chest radiography

Children usually present with symptoms of respiratory difficulty; therefore, chest radiography is always the first and most commonly performed test. Look for the position of the aortic arch, which is usually identifiable on the plain chest radiograph. The identification of a right aortic arch on chest radiograph in a child with airway difficulties, respiratory distress, or dysphagia should alert the clinician to a higher likelihood of a vascular ring. An ill-defined arch location is often observed in patients with double aortic arch. Such a finding should raise the suspicion of an arch anomaly in a symptomatic child. Other radiographic findings that may be noted with vascular rings include compression of the trachea and hyperinflation and or atelectasis of some of the lobes of either lung. A specific finding associated with anomalous left pulmonary artery is hyperinflation of the right lung. In general, chest radiography is not very sensitive in the diagnosis of vascular rings.

Barium esophagram

Most authorities consider barium esophagram to be the most important study in patients with a suspected vascular ring, and it is diagnostic in the vast majority of cases. However, in recent years, computer tomography and magnetic resonance imaging (MRI) have replaced this imaging modality as the primary source of information.

Double aortic arch (Figure 39.7) produces bilateral and posterior compressions of the esophagus, which remain constant regardless of peristalsis. The right indentation is

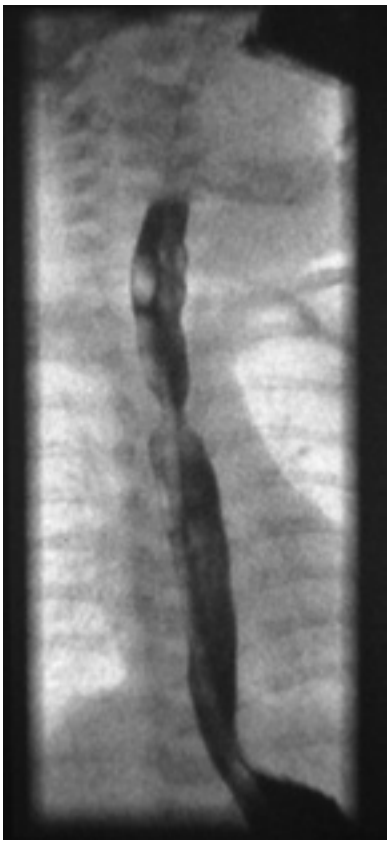

Figure 39.7 Barium esophagram in anteroposterior projection in a patient with double aortic arch.

usually slightly higher than the left, and the posterior compression is usually rather wide and courses in a downward direction as it goes from right to left. Patients having anomalies in which the right subclavian artery takes a retroesophageal course have a posterior defect slanting upward from left to right. The posterior defect in these cases is usually not as broad as that found in double aortic arch. In opposition, in patients with left aortic arch and aberrant subclavian artery, the oblique filling defect is mirror-imaged. An experienced radiologist can usually distinguish a double aortic arch from the retroesophageal subclavian artery based on the esophageal impression.[11]

An anterior indentation of the esophagus is, however, typical of an anomalous left pulmonary artery or so-called pulmonary artery sling. No posterior compression is present with this anomaly. Cases of abnormally located innominate artery causing tracheal compression have normal findings on esophagram.

Echocardiography and color-flow doppler

Echocardiographic studies have been increasingly used for the diagnosis of a vascular ring. This study has replaced pulmonary angiography at many centers to determine the presence of an anomalous left pulmonary artery. It is essential in the diagnostic workup of associated congenital cardiac defects. Some limitations in diagnosis using this study exist. Structures without a lumen, such as a ligamentum arteriosum or an atretic arch, have no blood flow and are difficult to identify with color-flow echocardiography. Also, identification of compressed midline structures and their relationship to encircling vascular anomalies may be difficult to detect, especially for the less experienced echocardiographer.

Computerized tomography scan, magnetic resonance imaging, and digital subtraction angiography

Computerized tomography (CT) scan, MRI, and digital subtraction angiography (DSA) can be useful diagnostic tools because they reveal the positions of vascular, tracheobronchial, and esophageal structures and their relationships to one another. These modalities provide excellent delineation of all of the associated structures. MRI has been proposed as an excellent substitute for angiography. All of these studies have drawbacks. CT scan and DSA expose the patient to radiation and require intravenous contrast. MRI requires patients to remain very still, so very young patients who are unable to understand verbal instructions require sedation. This may be particularly risky in young children with existing airway compromise. The expense encountered with these investigations must also be considered.

Aortic angiography and cardiac catheterization

In the past, diagnostic aortography was performed in selected cases to delineate the anomalous arch vasculature. It is generally agreed at present that echocardiography, CT scan, or MRI can usually provide the required information. However, reported cases exist of rare arch anomalies in which aortography was the only study from which the correct anatomic configuration was identified.[12] This study may be required in cases in which the diagnosis and arch configuration remain in question after other less invasive studies fail to provide a definitive answer. Cardiac catheterization is useful in cases in which associated cardiac abnormalities are known or suspected and echocardiography does not provide adequate diagnostic information.

Bronchoscopy

This diagnostic study has been used in the evaluation of children with symptoms of airway obstruction or compression. It is an essential part of the workup for congenital tracheal stenosis. It is rarely required in the diagnosis of the various types of complete vascular ring. In case a simple vascular ring was diagnosed by other tests, a bronchoscopy should not be performed, due to the added risks and costs.

In the presence of a vascular ring, pulsatile external tracheal compression is easily observed. Note that compression of the airway by a vascular structure in the pediatric patient

does not represent an unyielding obstruction and should not pose a problem for passage of the bronchoscope. In cases of an abnormally placed innominate artery, obvious pulsation is observed in the anterior wall of the trachea corresponding to the area of compression. A Kommerell diverticulum produces a pulsating tracheal obstruction placed in the membranous part of the trachea.

INDICATION FOR INTERVENTION

Surgical division of the vascular ring is indicated in any patient who is symptomatic with airway or esophageal compression.

Medical therapy

No medical therapy exists for the definitive treatment of vascular rings. Preoperatively, the patient should be given adequate nutritional support as well as general respiratory care and appropriate treatment of any respiratory tract infection. Surgery should not be delayed in the presence of a respiratory tract infection, because the division of the ring allows more adequate and complete clearing of respiratory secretions.

Surgical therapy

Surgical division of vascular rings causing clinical signs is the only appropriate form of therapy (Table 39.1). Surgery should be performed promptly after the diagnosis is made, especially in patients with stridor, apnea, or other symptoms of respiratory distress. Delay in operative intervention can result in complications of a serious nature. Left thoracotomy is the surgical approach of choice for the division of a vascular ring in the majority of cases. Anomalous left pulmonary artery sling has been corrected using the left thoracotomy approach in the past. More recently, the use of median sternotomy and cardiopulmonary bypass has been shown to produce better long-term results. The extremely rare configurations associated with left aortic arch and right descending thoracic aorta are the lesions that should be approached via a right thoracotomy for division of the ring. General anesthesia with a single-lumen nasotracheal or orotracheal tube is used for infants and small children. Bilateral radial arterial lines and a femoral arterial line together with oxygen saturation probes on all extremities are ideal.

DIVISION OF A DOUBLE AORTIC ARCH

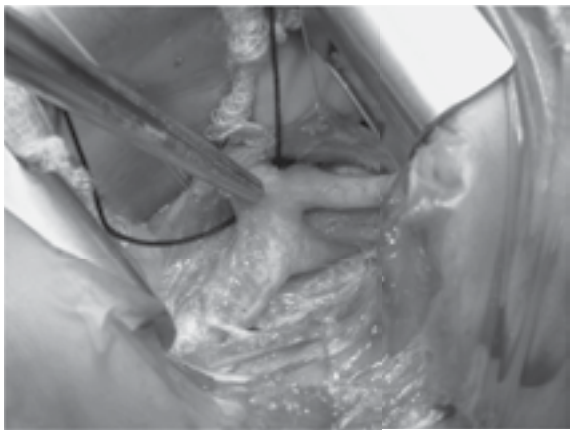
Traditional thoracotomy approach

The surgical approach to a double aortic arch is through a left thoracotomy in the fourth intercostal space with a muscle-sparing technique, and the components of the vascular ring are visualized. The pleura overlying the vascular ring should then be opened and careful dissection performed to clearly identify all the pertinent vascular structures (Figure 39.8a). The right, or posterior, arch does not require mobilization unless it is the lesser of the two arches and is to be divided. In such cases, the proximal descending aorta should be reflected anteriorly to visualize the area where the right arch enters.

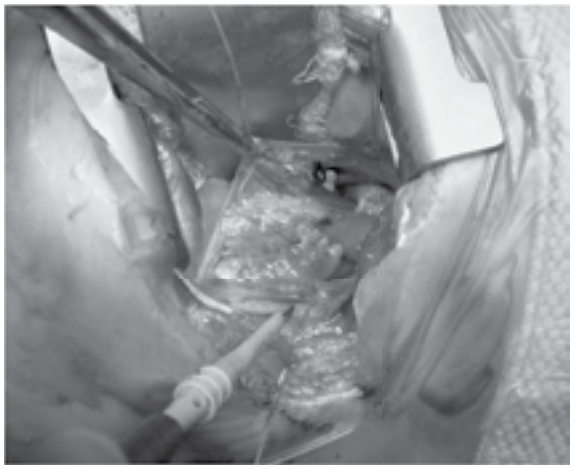
Table 39.1 Surgical management

Double Aortic Arch
Left thoracotomy in muscle-sparing technique—fourth interspace
Division of lesser of the two arches at insertion with descending aorta
Preserve blood flow to head and neck arteries
Ligate and divide ligamentum arteriosum
Leave pleura open
Right aortic arch with left ligamentum arteriosum
Left thoracotomy in muscle sparing technique—fourth interspace
Ligate and divide ligamentum arteriosum
If present, resect Kommerell diverticulum and transfer left subclavian to left carotid artery
Lyse adhesive bands
Leave pleura open
Pulmonary Artery Sling
Median sternotomy
Commence extracorporeal circulation
Resect left pulmonary artery (LPA) at its origin at the right pulmonary artery (RPA)
Oversew resulting defect in RPA
Reimplant LPA into main pulmonary artery anterior to trachea
Tracheal sling plasty for affected segment of trachealstenosis
Innominate Artery Compression Syndrome
Right anterolateral thoracotomy (left-sided thoracotomy also possible)—third or fourth interspace
Resect right lobe of thymus
Suspend innominate artery to posterior sternum
Postoperative bronchoscopy

The goal of surgical therapy is to divide the smaller of the two arches at a site that does not compromise the blood flow to the head vessels. A likely site for division of the minor, or atretic, arch is at its point of juncture with the descending aorta. Identify and avoid the recurrent laryngeal and vagus nerves. Before dividing the arch, it should be temporarily occluded and the anesthesiologist asked to check right and left radial and carotid pulses. Arch division should always be done between vascular clamps with oversewing of the divided stumps with nonabsorbable sutures. Simple ligation and division has been associated with ligature slippage and subsequent catastrophic hemorrhage. The divided stumps typically separate by 1.5–2 cm and disappear into the posterior mediastinum, making precise hemostasis quite



(a)



(b)

Figure 39.8 **(a** and **b)** Operative photograph taken during dissection after posterolateral thoracotomy in a patient with double aortic arch. The parietal pleura is opened, and the vascular structures are dissected. The left-sided ductus arteriosus is looped by a silk tie. The double aortic arch is divided by transaction and oversewing of the anterior arch at its junction with the descending aorta. The left-sided ductus arteriosus is tied, and only the aortic component is still visible. Note the resulting gap between the two stumps of the anterior aortic arch.

important. The operative repair is completed by freeing up all adhesive bands surrounding the esophagus in the area of the divided ring (Figure 39.8b).

Closure of the mediastinal pleura is not performed to avoid the development of adhesive scarring in the already affected area of the trachea and esophagus. The thoracotomy incision is closed without a chest tube by evacuating air from the pleural space with a small suction catheter. It may take up to 1 year for the child's noisy breathing to disappear as the tracheobronchomalacia caused by the ring resolves.

Video-assisted technique

A couple of groups advocate this technique as the method of choice for treatment of vascular rings, unless preoperative studies suggest that a patent segment of a double aortic arch is present.[13–15]

The patient is placed in right lateral decubitus position following single-lumen endotracheal intubation. Four small stab incisions are made in the posterolateral chest wall to admit from medial to lateral a grasping forceps, a lung retractor, a video scope, and an L-shaped cautery probe. Exposure is achieved by retracting the inflated left upper lobe inferiorly and medially. The mediastinal pleura is incised over the left subclavian artery, which leads to the other components of the vascular ring. The ring is dissected free from the esophagus and surrounding structures. The atretic segment of the vascular ring and ligamentum are identified. Clips are placed, and the ring and the ligamentum are divided between clips. Fibrous bands over the esophagus are also freed. A small chest tube is placed under direct vision, and the wounds are closed with Steri-Strips.[13,16]

RIGHT AORTIC ARCH

Surgical treatment of this condition also consists of dividing the ductus arteriosus or the ligamentum arteriosum. Division of the left subclavian artery is not generally necessary for relieving tracheal compression. Patients with an anomalous left subclavian artery and Kommerell[17] diverticulum are at risk of developing severe tracheal compression. Backer et al.[18–21] have recommended resection of the diverticulum and reimplantation of the left subclavian artery to the left carotid artery as a primary operation.[22] Surgery is performed through a muscle-sparing left lateral thoracotomy in the fourth intercostal space. As an alternative approach, the Kommerell diverticulum may be approached via median sternotomy. After dissection of the vascular structures and division of the ligamentum arteriosum, the patient is anticoagulated. Any adhesive bands are lysed, and the recurrent laryngeal and phrenic nerves are carefully identified and protected. The base of the Kommerell diverticulum is taken in a side-biting clamp, and the distal subclavian artery is occluded with a vascular clamp prior to its division. The diverticulum is resected and its base oversewn. The left subclavian artery is then anastomosed to the origin of the left carotid artery. This anastomosis may be performed more easily via the sternotomy approach.

PULMONARY ARTERY SLING

Although the traditional approach has been through a left-sided thoracotomy with reimplantation at the original site of the left pulmonary artery as performed in 1953 by Potts et al.[3] and then reimplantation of the left pulmonary artery on the left side of the main pulmonary artery as described by Hiller and MacLean,[23] currently, the preferred method is to undertake repair via median sternotomy. With this approach and utilizing cardiopulmonary bypass, reimplantation of the left pulmonary artery onto the left side of the main pulmonary artery without application of a side-biting clamp is carried out without aortic cross-clamping. If tracheal repair is necessary, it can be performed thereafter, or

tracheal repair is performed on cardiopulmonary bypass and the left pulmonary artery is relocated in front of the trachea after extensive dissection of the left pulmonary artery into the left hilum. This technique was introduced by Kirklin and Barrat-Boyes.[24] Different techniques are utilized for tracheal repair depending on the length and site of the tracheal stenosis. Over recent years, many different types of repair have been undertaken, including simple end-to-end repair,[25,26] various forms of patch tracheoplasty,[27,28] tracheal homograft implantation,[29,30] and slide tracheoplasty.[31–36] In recent years, slide tracheoplasty has been favored by most groups.

A review of these methods is beyond the scope of this chapter, but more comprehensive reviews are available.[20,21,35–40]

LEFT AORTIC ARCH WITH ANOMALOUS ORIGIN OF THE INNOMINATE ARTERY

The surgical treatment of this anomaly is based on the suspension of the innominate artery from the posterior aspect of the sternum. This operation can be performed from either side.[41,42] The thymus lobe of the corresponding side is resected and the pericardium opened respecting the phrenic nerve. The ascending aorta or the innominate artery is approximated to the posterior aspect of the sternum by two or three interrupted pledget-supported heavy sutures. Bronchoscopy is then performed to confirm the tracheal relief. In order to relief the compression of the trachea it is essential not to dissect a plane between the great vessels and the trachea, so the tension applied by the suture on the vessels is transferred to the trachea's anterior wall.

Other authors have described using a median sternotomy with division of the innominate artery and reimplantation into the ascending aorta at a site more rightward and anterior to the native site.[43] This technique sacrifices the active suspending mechanism on the tracheal wall provided by the classical suspension maneuver. In addition, there seems to be some risk of cerebrovascular accident, although Grimmer et al.[44] report no cerebrovascular injury in a long-term follow-up study.

Results

TRADITIONAL THORACOTOMY APPROACH

One of the largest reports of vascular anomalies causing tracheoesophageal compression comes from Backer et al. from the Children's Memorial Hospital in Chicago, United States, published in 1989[10] and updated in 2005.[19] The authors described 204 infants and children with a mean age of 13 months who had undergone surgical procedures for tracheoesophageal obstruction. Of these, 113 patients had a vascular ring, 61 with a double aortic arch and 52 with a right aortic arch and left ligamentum. The operative mortality rate was 4.9% with a late mortality rate of 3.4%. However, there were no operative deaths within the last 28 years. At a mean follow-up of 8.5 years, 92% of the patients were essentially free of symptoms.

In 1994, Cordovilla Zurdo et al.[45] from Madrid, Spain, reported on a series of 43 patients with one hospital and one late death. Over a mean follow-up of 11 years, 90% of the patients were asymptomatic. Similarly, Anand et al.[46] from Atlanta, Georgia, United States, reported on 44 patients operated on for vascular ring or pulmonary artery sling in the period of 1977–1990. In this series, three deaths due to cardiac failure after repair of complex anomalies were reported.

Further studies report on good long-term results with low operative mortality. Mortality seems to be limited and only occurring in patients with complex cardiac anomalies.[47–50]

Video-assisted technique

At the moment, only a limited number of publications are available reporting on results after thoracoscopic division of vascular rings.[13–16] In these series, no mortality was observed. However, stay in the intensive care unit (ICU) and in the hospital was not different from the conventional technique. It should be taken into account that this technique offers only a limited amount of control, and in addition, the surgical times are much longer than the conventional procedures. In addition, the video-assisted technique is only applicable if the vascular structures to be divided are obliterated.

Pulmonary artery sling with tracheal repair

Kocyildirim from Great Ormond Street Hospital for Children, London, United Kingdom, reports in his study on 34 patients with long-segment tracheal stenosis (21 patients with pulmonary artery sling). Cardiopulmonary bypass was used in all operations. Before the establishment of the multidisciplinary tracheal team, pericardial patch tracheoplasty was performed in 15 of 19 patients. Twelve patients had a suspended pericardial patch tracheoplasty, 2 (17%) of whom died late after the operation. Of 3 patients who had had a simple unsuspended patch, 2 (67%) died early after the operation. Four patients were operated on with the tracheal autograft technique, 2 (50%) dying early in the postoperative period. After multidisciplinary tracheal team formation, in the era between 2001 and 2004, 15 patients were operated on with slide tracheoplasty, and there were 2 (13%) early postoperative deaths. A significant reduction in cost and duration of stay has been shown in both the ICU and the hospital.[51]

Backer from the Children's Memorial Hospital in Chicago, United States, reports on 28 infants after pericardial tracheoplasty for long-segment tracheal stenosis. Seven of these infants required reoperation or stenting for residual or recurrent tracheal or bronchial stenosis. Revisions were performed 2–6 months after the original procedure with cardiopulmonary bypass and bronchoscopic guidance. Two patients underwent repeat pericardial patch tracheoplasty, and four patients underwent insertion of a rib cartilage graft. Two of these patients required Palmaz wire expandable stents, and one other patient also underwent stent placement. There was one late death 1 year after cartilage graft insertion. The authors identified three risk

factors for reoperation after tracheoplasty: younger age at initial surgery and associated pulmonary artery sling or tracheal right upper lobe bronchus. Good intermediate results are possible in this difficult group of children using a selective and inclusive strategy for tracheal enlargement that includes repeat pericardial tracheoplasty, autologous cartilage grafts, and expandable wire stents.[52,53]

CONCLUSION AND FUTURE DIRECTIONS

Nowadays, children presenting with tracheal or esophageal obstructions caused by congenital vascular malformations can be treated with low morbidity and a minute mortality. Conventional surgery involving thoracotomy or median sternotomy is still the standard of treatment. Minimally invasive approaches have been developed, but further technical advances are necessary to promote a wider dissemination of these techniques.

Pulmonary air leaks

PREM PURI AND JENS DINGEMANN

INTRODUCTION

Pulmonary air leaks include urgent life-threatening neonatal emergencies like pulmonary interstitial emphysema (PIE), pneumomediastinum, pneumothorax (PT), or pneumopericardium.[1–4] The incidence of pulmonary air leaks in the neonates has increased in recent years, possibly because an increasing number of sick infants with respiratory distress on assisted ventilation are now surviving to develop this complication.[5] The sequence of events in the occurrence of pulmonary air leaks is similar regardless of whether it is caused by uneven alveolar ventilation, air trapping, and high transpulmonary pressure swings. The rupture of terminal air sacs causes air to escape into the pulmonary interstitium, resulting in pulmonary interstitial emphysema. The air tracks along the sheaths of pulmonary blood vessels to the lung hilum and air may then rupture into mediastinum, pleura, or pericardium.[6] It has also been suggested that air directly enters the pleural cavity following a rupture of a subpleural bleb.[7] Rarely systemic air embolism may be a terminal event of pulmonary air leaks.

PULMONARY INTERSTITIAL EMPHYSEMA

PIE is predominantly seen in preterm infants with respiratory distress syndrome (RDS) who are on assisted ventilation.[8] Occasionally, it follows vigorous resuscitative efforts. The lesion represents air that has dissected along perivascular sheath within pulmonary interstitium. The compression caused by interstitial "air conduits" interferes with ventilation and reduces pulmonary perfusion leading to CO_2 retention and hypoxemia.

The incidence of PIE increases with low birth weight (LBW) and prematurity. In one series, 20 out of 303 ventilated LBW babies developed PIE,[9] but significantly high incidences of 32% and 42% have been reported in other series.[10,11]

Presentation and diagnosis

PIE may be diffuse or localized. Transillumination of the chest with diffuse PIE will give the same appearance as a large pneumothorax.[12] However, chest x-ray is the method of choice to diagnose PIE. The radiological features consist of hyperinflation and multiple cyst-like lucencies that appear to radiate outward from the hilum of the lung (Figure 40.1). Suspect neonates should be monitored by daily chest x-ray for an earlier diagnosis of PIE. At a later stage, large bullae may appear. The localized form of PIE may be misdiagnosed as cystic adenomatoid malformation of the lung.

Treatment

PIE, diffuse or localized, makes ventilatory management difficult. It is mandatory to use appropriate ventilation strategies to prevent PIE or its deterioration, respectively. Ventilatory pressures should be kept at a safe minimum while aiming for acceptable blood gas values of PaO_2 > 6–7 kPa, pH > 7.25, and $PaCO_2$ < 8 kPa.[13]

No specific surgical treatment is indicated for diffuse PIE. Benefit has been demonstrated for both High Frequency Positive Pressure Mechanical Ventilation (HFPPV) and triggered ventilation with regard to a reduction in air leak and a shorter duration of ventilation.[13] Also the prophylactic application of surfactant has been shown to be beneficial for the outcome of preterm infants with PIE.[14] If the disease is unilateral or localized, selective partial or complete atelectasis of the desired segment can be achieved by selective bronchial intubation[15,16] or by placing the infant with his or her hyperinflated lung dependent in the lateral decubitus position at all times.[17]

An aggressive approach of decompressing the lungs and creation of artificial pneumothorax has been described for patients in whom conservative management fails. This approach has been shown to successfully remove interstitial gas, and after re-evacuation of the pneumothorax, ventilation could be discontinued shortly.[18]

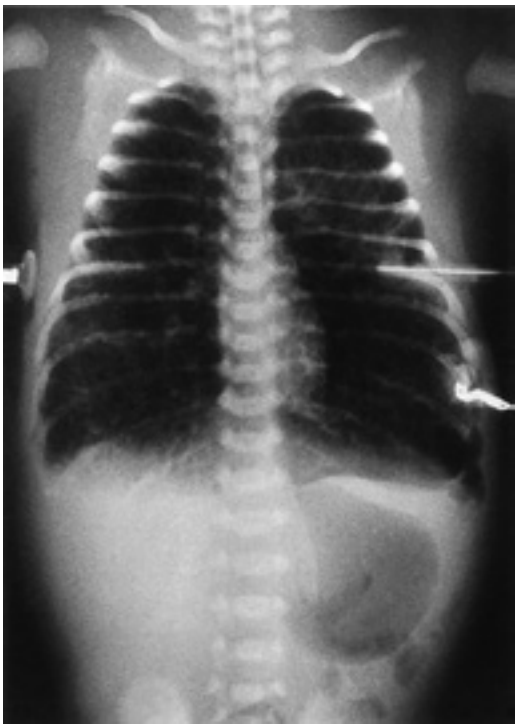

Figure 40.1 Diffuse PIE in a baby weighing 1200 g and requiring prolonged positive pressure ventilation for hyaline membrane disease. The lungs are grossly hyperinflated with a diffuse cystic pattern in this film at 7 days of life. Note narrow heart shadow due to tamponade effect of the distended lungs. A shallow pneumothorax is present in the left upper zone and a left chest drain has been inserted.

Surgery is reserved for patients in whom conservative or interventional therapy failed. However, localized PIE has been successfully treated by atypical wedge resection[19] and lobectomy.[20]

Prognosis

The mortality rate from diffuse PIE has been reported to be from 24% to as high as 60%.[9,21] There have been no significant differences in neonatal parameters between infants who died or survived. However, the survivors had a significantly lower maximal peak inspiratory pressure and FiO_2 on the first day of ventilation.[21]

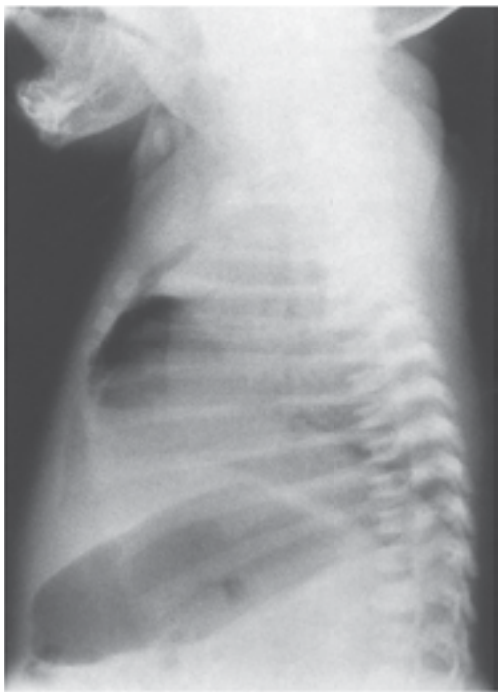
PIE is invariably fatal in the group of neonates with RDS who weigh <1600 g at birth and who develop bilateral PIE within the first 48 hours of life, needing FiO_2 above 0.6 on the first day. High positive inspiratory pressure on day 1 was found to be the most significant parameter associated with fatal PIE. A cutoff level of 26 cmH_2O was found to be discriminant.[22] These criteria may be useful in selecting neonates who might benefit best from the new modes of ventilation. In preterm infants, additional application of surfactant significantly reduces the mortality of PIE.[14] In the survivors, diffuse PIE greatly increases the incidence of bronchopulmonary dysplasia, contributing to the long-term sequelae of RDS in preterm infants.[12]

PNEUMOMEDIASTINUM

Pneumomediastinum develops when interstitial air in PIE migrates to the mediastinum. Also spontaneous pneumomediastinum without any history of mechanical ventilation or concomitant lung disease has been reported.[23] If the collection of air is small, it remains asymptomatic. However, large collections of mediastinal air may produce respiratory distress.[23] Heart sounds are muffled and the sternum may appear bowed.

The diagnosis is made on chest x-ray. The anteroposterior views may show the characteristic "angel-wing" sign produced by air elevating the thymus gland (Figure 40.2a).

(a)



(b)

Figure 40.2 Pneumomediastinum. **(a)** Anteroposterior view demonstrates the characteristic "angel wing" sign produced by air elevating the thymus from the heart. **(b)** Lateral view confirms air in the anterior mediastinum.

It has also been described as having a crescentic configuration resembling a "spinnaker sail."[4] Lateral x-ray of the chest shows marked hyperlucency in the anterior mediastinum (Figure 40.2b). Ultrasound can be used to diagnose pneumomediastinum. It has been reported to be superior to x-ray under certain conditions and should be considered if a pneumomediastinum is clinically suspected and x-ray shows no typical findings.[24]

Retrocardiac pneumomediastinum has a strong association with other manifestations of extra-alveolar air leaks such as PIE, pneumothorax, dissection of air into the soft tissues of the neck, and pneumoperitoneum. Tension pneumomediastinum has also been described to cause isolated left ventricular inflow obstruction. Symptomatic pneumomediastinum is managed by ultrasound-guided needle aspiration of the anterior mediastinal compartment.[25] Successful chest tube insertion into the anterior mediastinum under ultrasound guidance has also been described in a preterm infant with tension pneumomediastinum in whom initial needle aspiration had not led to relief of symptoms. In asymptomatic cases, air is absorbed spontaneously and no treatment is indicated.

PNEUMOTHORAX

Pneumothorax is far more frequent in the newborn period than in any other period of life—symptomatic pneumothorax occurs in 0.08% of all live births[26] and in 5%–7% of infants with birth weight of ≤1500 g.[27,28] It is bilateral in about 20% of cases.[29] Pneumothorax in the newborn predominantly occurs in patients with hyaline membrane disease, meconium aspiration syndrome, pulmonary hypoplasia, and infants requiring vigorous resuscitation at birth.[29–31]

In ventilated preterm infants, it has been shown to be attributed to high peak inspiratory pressure low Fio_2, pulmonary hemorrhage, and high arterial CO_2, while a decreased risk was associated with high positive end-expiratory pressure.[32]

The overall incidence of pneumothorax in the newborn with respiratory difficulties has been reported to be as high as 34% of those who are ventilated.[33] Pneumothorax can also be caused as a complication of deep endotracheal tube suction[34] and by other iatrogenic perforation of the bronchus. A rare association of spontaneous pneumothorax with congenital cystic adenomatoid malformation[35] and early spontaneous pneumothorax with common pulmonary vein atresia[36] have been reported. The "surgical" cases of pneumothorax and/or pneumomediastinum at the Liverpool Neonatal Surgical Centre included infants with gross renal anomalies, large exomphalos, a rare type of vascular sling, and spontaneous perforation of esophagus. In half of the cases, the etiology was less obvious.[37]

PRESENTATION AND DIAGNOSIS

Pneumothorax should be suspected in infants with respiratory distress who suddenly deteriorate. Tachypnea is a uniform finding and is often accompanied by grunting, chest retractions, and cyanosis. Physical findings in unilateral pneumothorax include a shift of the cardiac impulse to the unaffected side, diminished or absent breath sounds, and a hyperresonant percussion note on the affected side. In tension pneumothorax, arterial hypotension, apnea, and bradycardia are usually the initial signs.

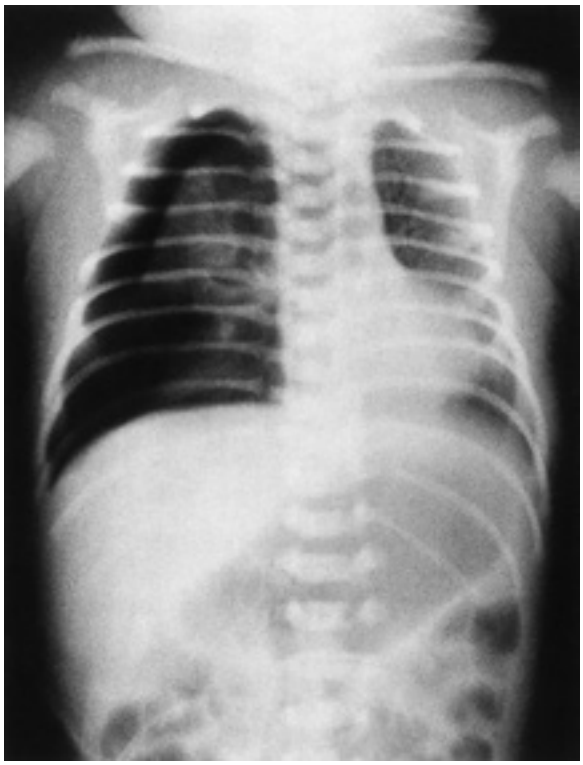


Figure 40.3 Right pneumothorax complicating interstitial emphysema in an infant with hyaline membrane disease. Note air lucency around right lung with absence of lung markings. The mediastinum is shifted to the left, indicating tension.

A large pneumothorax can be diagnosed by transillumination using a high-intensity light with fiber-optic probe.[38] The advantage of this method is the rapidity with which large life-threatening pneumothoraces can be diagnosed and treated. The gold standard for diagnosis is radiography of the chest. A large pneumothorax is easily recognizable in infants by identification of the visceral pleural line, which is most readily seen over the apex and along the costal surface of the lung (Figure 40.3). Other important observations in pneumothoraces are a mediastinal shift and absence of lung markings. Small volume pneumothoraces are more difficult to identify, and in these cases, lateral decubitus cross-table views are very helpful in showing the rise in pleural air to the lateral or medial side of the hemithorax (Figure 40.4). Rarely, lobar emphysema, congenital cystic adenomatoid malformation, or congenital diaphragmatic hernia may resemble pneumothorax in the chest x-ray.[12]

TREATMENT

Most small pneumothoraces with no symptoms need only close observation and monitoring in a neonatal intensive

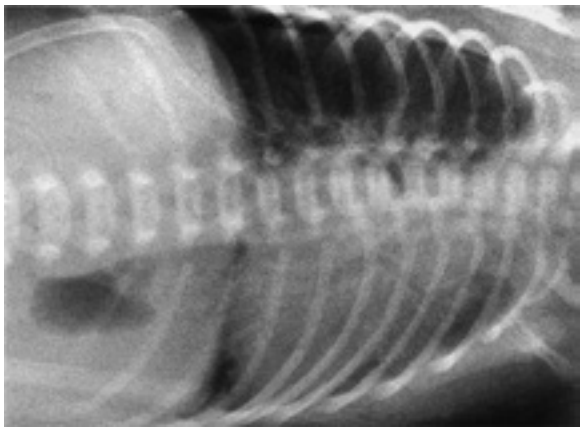

Figure 40.4 Small-volume pneumothorax demonstrated in the lateral decubitus view with the right side raised.

care unit.[39] The ventilatory management should aim to keep pressures at lower acceptable values including the use of patient-triggered ventilation and high-frequency positive pressure ventilation[13] such as adjuvant neuromuscular paralysis of the infant.[40] A pneumothorax should be drained in the following situations:

- Radiological signs of tension pneumothorax
- Cardiorespiratory symptoms
- Infants on intermittent positive pressure ventilation, even if asymptomatic

The infant should be temporarily disconnected from the ventilator during the introduction of a chest drain or aspiration of a pneumothorax to avoid the risk of lung damage.[41]

In a desperately ill neonate, a life-saving emergency needle aspiration of a tension pneumothorax can be done before formal insertion of a chest drain. A butterfly (18-gauge) or i.v. cannula with a three-way tap and a 20 ml syringe can be used for decompression. Aspiration is performed through the second intercostal space in the midclavicular line. The insertion of the needle is oblique through the muscle plane to avoid entry of air once the needle is removed. Occasionally a single aspiration may be enough, but all these babies must be closely observed and monitored clinically and radiologically as nearly all of them require a tube thoracostomy on follow-up.

Tube thoracostomy is required in the majority of cases. A chest drain (10–14 French gauge) is inserted through the second intercostal space in the midclavicular line or the sixth space in the mid-axillary line under local anesthesia. The tip of the chest tube should be placed anteriorly retrosternally for better drainage.[42] A purse-string stitch around the site of the catheter insertion is not necessary in neonates. The insertion site should be closed with a waterproof adhesive plastic film to avoid any air leak. After fixing the catheter firmly, it is connected to an underwater seal drain with or without a low-grade suction of 5–10 cmH_2O. Once the lung is expanded and stable, the tube can then be removed. A chest film after removal of the tube to ensure that a pneumothorax has not recurred should only be done if this is clinically suspected.

Use of conventional chest drains is not free from complication as they can cause lung perforation[41] or phrenic nerve injury related to abnormal location of the medial end of the chest tube.[43]

There are pigtail pleural drainage catheters available, which have been designed to prevent iatrogenic damage of intrathoracic organs.[44] However, even these catheters made from softer material can be the cause of pulmonary injury in premature infants.[45] Another option is the insertion of ordinary 18G venous catheters, which have been proven to be a quick, effective, and safe alternative to drain neonatal pneumothorax. In the majority of cases, a properly sized ordinary chest drain with an underwater seal or with a vacuum-control unit should be adequate. The Heimlich flutter valve, though useful clinically, adds to the resistance of the system, especially if fluid accumulates in the valve.[46]

Prognosis

Cases with pneumothoraces without underlying lung disease have a good prognosis. The mortality, though not the incidence, varies with birth weight and is, in general, double that of babies who have RDS but no air leak.[12] In one series of infants presenting with pneumothoraces within the first 24 hours of life, the overall mortality rate was 52%.[47] The mortality rate is inversely proportional to the infant's birth weight: 53% in infants with birth weights <1 kg.[48] The incidence of grades 3 or 4 intraventricular hemorrhage in infants with pneumothoraces associated with arterial hypotension is 89% as compared with neonates with pneumothoraces associated with normal blood pressure, which is only 10%.[49] This can have a detrimental effect on the neurological outcome. Ventilatory parameters may be helpful in making a prognostic assessment. The survivor group responds well to a fraction of inspired oxygen of less than 70% and a PEEP of 6 cm or less. A CO_2 retention associated with pneumopericardium and PIE is an unfavorable sign.[47]

Pneumopericardium

Pneumopericardium is the least frequent pulmonary air leak. However, recently, it has been occurring with increasing frequency as a complication of ventilatory therapy. Pneumopericardium can develop while the patients are on high-frequency ventilation respiratory support.[50] Neonatal pneumopericardium has also been reported during nasal continuous positive airway pressure (CPAP) ventilation and in a full-term neonate following a forceps delivery and mild asphyxia. The exact etiology of pneumopericardium is not known; it is probably interstitial pulmonary air, secondary to alveolar rupture, which dissects into the mediastinum and then enters the pericardial space at the reflection of the pericardium onto the great vessels.

The pneumopericardium may be asymptomatic or symptomatic. Asymptomatic infants do well without any

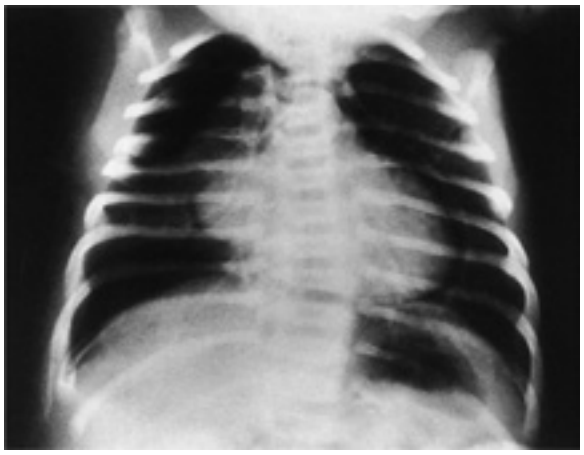

Figure 40.5 Pneumopericardium in a 2-day-old full-term infant with complicating meconium aspiration. Note right pneumothorax also.

treatment. The clinical signs in symptomatic patients are those of cardiac tamponade, i.e., a sudden onset of bradycardia, muffled heart sounds, cyanosis, and hypotension. Changes in ECG axis and/or voltage may be observed. The classic radiological finding is a continuous radiolucent band of air that conforms to the cardiac outline and does not extend beyond the level of the great vessels (Figure 40.5). Extra ventilatory air (PIE and pneumomediastinum) is present in over 90% of patients. Simple needle pericardiocentesis is the appropriate therapy for most cases with cardiac tamponade. However, a few babies with pneumopericardium uncontrolled by needle aspiration require placement of a pericardial catheter for continuous drainage of air.

Pneumopericardium can be masked by other pulmonary air leaks and should be considered if drainage of the primarily obvious site does not improve the cardiorespiratory status of the infant.[3] The mortality rate in infants with pneumopericardium is high, especially in preterm infants.[3,12]

Chylothorax and other pleural effusions in neonates

MIHO WATANABE, BELINDA HSI DICKIE, AND RICHARD G. AZIZKHAN

INTRODUCTION

Pleural effusions in neonates and children can present as a spectrum from asymptomatic small accumulations of fluid to life-threatening collections that could result in compression of the lung parenchyma and/or mediastinal shift.

Pleural effusions in neonates are rare, at an estimated 5.5–220 per 10,000 deliveries. In fetuses and neonates, the most common cause of congenital effusions is a chylothorax. A well-established entity, chylothorax results from leakage of chyle from the thoracic duct into the pleural cavity. The most common etiology of acquired pleural effusion in newborns is iatrogenic (result of cardiac or thoracic surgery).[1–3] In the older child, parapneumonic effusions due to empyema are the leading cause of effusions, followed by congestive heart failure and malignancy.[4–6] It is very important to recognize the diagnosis early so as to provide appropriate treatment and limit morbidity.

This chapter presents a basic description of the pathophysiology of pleural effusion and chyle, the anatomy and embryology of the pleura and lymphatic system, and an overview of key clinical aspects of neonatal pleural effusions, especially chylothorax, as well as fetal pleural effusion, hemothorax, and empyema, to provide the foundation for understanding this disorder.

PATHOPHYSIOLOGY

Normally, with the thoracic cavity, there is a small amount of thin fluid (~0.3 mL/kg).[7] The function of the pleural fluid is to lubricate the pleura to allow for smooth lung movement and to provide surface tension of the lung to keep the appropriate distance from the thoracic wall. Fluid continuously moves from the parietal pleura though the pleural space to be absorbed by the visceral pleura.[8] The fluid then drains into the lymphatic system via the thoracic duct.[9] The volume of fluid in the pleural space is minimized by a balance of starling forces, oncotic pressure in the circulation, and negative pressure in the lymphatics of the thorax. Recently, another hypothesis states that the amount of fluid can be controlled and absorbed via a metabolically active transport system in the parietal pleural mesothelial cells.[10,11] Turnover of the pleural fluid is estimated to be about 0.15 mL kg/hour, and any interruption in the flow of the fluid may significantly increase the volume within the thoracic cavity. Therefore, accumulation can occur when the balance between the rate of filtration and lymphatic clearance is altered. This can be seen in increased systemic capillary or venous pressure, increased capillary vessel permeability due to infection or inflammation, decreased plasma colloid osmotic pressure, increased negative intrapleural pressure, obstructed lymphatic flow, or abnormality or injury of the lymphatic system.

Chyle is defined as a mixture of lymph and chylomicrons. Chylomicrons (emulsified fat globules) are absorbed from the small intestine, and are mixed with clear lymph from the pelvis and lower extremities, conducted centrally, and then drained into the venous system via the thoracic duct. At birth, chyle is clear and straw colored; soon after milk feeding begins, chylomicrons render it milky white. The fat content of the fluid varies between 0.4 and 4.0 g/100 mL, with a triglyceride content of >500 mg/100 mL. Variation is dependent on the amount of milk ingested. Lymphocyte counts in chyle are high (80%–100%) and are predominantly T cell.[12] The protein and electrolytes in chyle are similar to those in plasma. The volume of chyle loss per day can exceed 1.7 times the patient's blood volume, resulting in a serious state of depletion characterized by hyponatremia, hypoproteinemia, metabolic acidosis, and lymphocytopenia.[13]

ANATOMY

The lymphatic system is a one-directional circulatory system that transfers extracellular fluid, lymph, and chyle from peripheral tissues to the subclavian vein without a central pump. Lymph is collected in the cisterna chyli and reaches the venous system via the thoracic duct, which ascends in the posterior mediastinum between the azygos vein and the descending aorta. This duct crosses to the left at the level of the fifth thoracic vertebra, continues its ascent into the neck on the left of the esophagus, and opens into the venous system at the confluence of the internal jugular and subclavian veins. In the thorax, it receives lymph from the parietal pleura of both sides via several collecting trunks. Lymphatic branches from structures in the posterior mediastinum and from the left lung and its pleura join to form the left bronchomediastinal trunk; this trunk opens into the thoracic duct or directly into the great veins. There are also several potential lymphatic–venous communications that may function when the main duct is traumatized or blocked.

While the thoracic duct is usually a singular structure, its embryology underscores the potential for anatomic variations and congenital anomalies. It may develop in different anatomical patterns with several lymphaticovenous anastomoses. Variation in lymphatic pathways and the presence of accessory lymphatic channels can account for chylous effusions resulting from surgical procedures that do not expose the main thoracic duct. Trauma to the duct in the posterior mediastinum can produce a unilateral or bilateral chylothorax. Increased intraductal tension leads to drainage of chyle into the thorax. Rupture of the thoracic duct between the diaphragm and T5 usually produces a right-sided chylothorax, and above T5, a left-sided chylothorax. Rupture in the midline at T5 or as part of a more diffuse lymphatic condition causes bilateral chylothorax.

EMBRYOLOGY

The lymphatic system begins to develop at the end of week 5, approximately 2 weeks later than the cardiovascular system. One hypothesis states that lymphatics develop as diverticula of the endothelium of the adjacent veins, establishing venous endothelium as the primordial structure of the lining of the lymphatic system.[14] In weeks 6–9, the lymphatic channels are developed as outgrowths of the venous endothelium in six original lymph sacs and dilate locally—two jugular lymph sacs, two iliac lymph sacs, one retroperitoneal lymph sac, and one cisterna chyli dorsal to the retroperitoneal lymph sac. These sacs branch into the tissues to form the jugular sacs, iliac sacs, and retroperitoneal and cisternal sacs. The lymph sacs except the cisterna chyli are transformed into groups of lymph nodes around the third gestational month.

ETIOLOGY

Twenty-three to thirty-two percent of neonatal pleural effusions are congenital. The main cause of the effusions is chylothoraces, but other causes are associated with hydrops fetalis, congenital anomalies, and genetic abnormalities.[3,15]

Congenital chylothorax

Chylothorax can present in utero or in the neonatal period. Males are affected twice as frequently as females, and 60% of cases involve the right side of the chest.[16] The occurrence of congenital chylothorax in the absence of other disease suggests the existence of congenital malformation of the lymphatic system or the thoracic duct, resulting in the leakage of chyle into the pleural space.[17] The malformation can be congenital atresia of the thoracic duct or congenital fistula due to failure of peripheral lymphatic channels to communicate with the major lymphatic network. Congenital chylothorax can also be associated with other congenital malformations (76%), chromosomal anomalies (trisomy 21) (12%), and other syndromes (Noonan, Turner) (6%).[3] Congenital chylothorax is usually bilateral, with low Apgar score and occasional need for immediate thoracocentesis.

Congenital pleural effusion with associated diseases

Congenital pleural effusion is also associated with hydrops fetalis, other congenital anomalies, or genetic abnormalities.[3]

Hydrops fetalis is a serious fetal condition defined as abnormal fluid accumulation in two or more fetal compartments, including ascites, pleural effusion, pericardial effusion, and skin edema. The underlying cause is an imbalance of interstitial fluid production and subsequent lymphatic return. The causes of hydrops fetalis are (1) immune hydrops fetalis (Rhesus blood group isoimmunization of the fetus) and (2) nonimmune hydrops fetalis (major causes are cardiovascular disorder and lymphatic dysplasia, followed by thoracic disorder, hematologic disorder, twin pregnancy, infection, genetic syndromes, and chromosomal abnormalities). Nonimmune hydrops is more common than immune hydrops. The pathogenesis of pleural effusion in these diseases is incompletely understood, but multiple features for dysregulation of the net fluid movement would be involved. Pleural effusion in hydrops can be either chylous, transudate, or exudate. In contrast, pleural effusion with other congenital anomalies or genetic abnormalities is mostly transudate but can be chylous.

Acquired pleural effusions

IATROGENIC ACQUIRED PLEURAL EFFUSIONS

Acquired pleural effusion results primarily from iatrogenic insult, surgery, or trauma to the thorax (61%–74%).[3] Recent studies suggest an increase in the prevalence of postoperative chylothorax from the previously reported 1% or less to 2.5%–4.7%.[18–20] This has been attributed to the increased complexity of the surgery being performed and possibility of the earlier reintroduction of feeding after surgery. Iatrogenic injury can occur during surgery in the region of

the aortic arch for conditions such as patent ductus arteriosus, coarctation of aorta, vascular ring, and other congenital cardiovascular anomalies[20,21] as well as during esophageal repair or repair of congenital diaphragmatic hernia.[22,23] Acquired iatrogenic pleural effusions are mainly chylothorax (65%). Acquired iatrogenic pleural effusions can also be a manifestation of a complication of subclavian and internal jugular venous cannulation and/or superior vena caval obstruction secondary to previous catheterization, chest tube insertion, and traumatic delivery. Acquired iatrogenic pleural effusion is often unilateral, on the left side.

NONIATROGENIC ACQUIRED PLEURAL EFFUSIONS

The etiology of noniatrogenic acquired pleural effusion includes empyema, superior vena cava syndrome, hypoproteinemia, heart failure, and renal failure. There have been rare reports of infantile chylothorax resulting from abdominal blunt trauma due to child abuse.[24,25] It is sometimes difficult to determine the cause of noniatrogenic acquired pleural effusion.

CLINICAL SYMPTOMS

Symptoms of pleural effusion are very broad depending on the volume, compression of the lung, and displacement of the mediastinum. Tachypnea, dyspnea, retraction of chest wall, and cyanosis are typical presenting signs and symptoms. On examination, dullness and diminution of breath sounds on the affected side and displacement of the heart and mediastinum to the opposite side can be found. Chest pain can be one of the symptoms in the older child due to irritation of the parietal pleura; however, it can also be referred pain to the thoracoabdominal wall (intercostal nerves) or to the shoulder (phrenic nerve).

In cases of congenital pleural effusion, symptoms of respiratory distress may be noted shortly after birth or at any time up to 2 weeks of life. In contrast, the interval between surgery and the occurrence of acquired pleural effusion can vary from 1 to 25 days. The time is shortest when there is a direct injury to the duct (5–7 days) and longest when there is high pressure or thrombosis of the vena cava (10–14 days). Chyle may accumulate in the mediastinum for several days before extravasating into the pleural space.

The loss of large quantities of chyle over a period of time produces nutritional failure, metabolic acidosis, sepsis, and renal failure. Significant loss of protein and lymphocytes can result in lymphocytopenia and hypogammaglobinemia, causing immune deficiencies and abnormal cell-mediated immune responses.

DIAGNOSIS

Radiology

Chest radiographs will typically show opacification of one or both hemithoraces, with or without compression of the lung and displacement of mediastinal structures in unilateral pleural effusion (Figure 41.1). Radiographic diagnosis in premature infants may, however, be difficult, because most of these infants already have significant pulmonary disease, and chest radiographs may appear to have areas of increasing consolidation rather than the more typical layering of pleural fluid seen in older children.

Ultrasonography is a reliable diagnostic method to detect pleural effusion in neonates and children. Its use in obstetric practice as the primary method of imaging the fetal chest has led to the increasing frequency with which in utero diagnosis can be made.

Other modalities such as computerized tomography (CT) scan, lymphangiography, and lymphoscintigraphy can be helpful. Lymphangiography involves injection of a contrast agent into the lymphatic system and following the lymphatic flow proximally. Simultaneous CT or magnetic resonance imaging (MRI) can better delineate the lymphatic anatomy and define the site of leak or obstruction. Lymphoscintigraphy uses injection of a radionuclide (commonly 99m-technetium) either intradermally or subcutaneously to outline the network of the lymphatics.

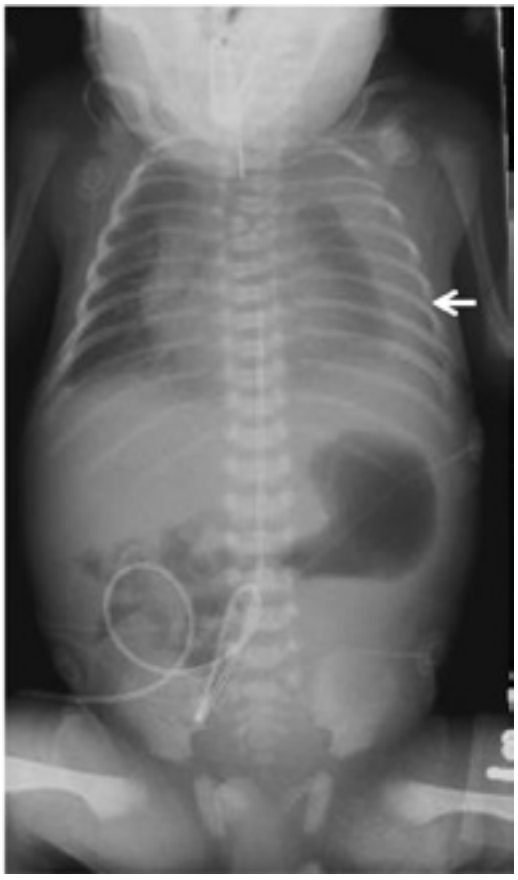

Figure 41.1 Radiographic images of fetal bilateral pleural effusions. X-ray (anteroposterior view) of neonate with unilateral pleural effusion (arrows), demonstrating a moderate left pleural effusion with mild rightward mediastinal shift.

Laboratory testing

Analysis of the pleural fluid is used to help diagnose the cause of pleural effusion and to differentiate types of pleural effusion (transudate, exudate, chylothorax, emphysema, hemothorax, total parenteral nutrition [TPN] leakage). Pleural effusion is drained by thoracentesis or chest tube placement. The fluid should be sent for diagnostic analysis including (1) microscopic examination for fluid characteristic and cell count, (2) pleural fluid biochemistry, (3) cytology, and (4) Gram stain and culture for bacterial or fungal infection. Normal pleural fluid is usually clear, with a composition of pH of 7.60–7.64, protein less than 1–2 g/dL, white blood cells (WBCs) fewer than 1000/mm^3, glucose similar to that of plasma, and lactate dehydrogenase (LDH) less than 50% of plasma.

Chylothorax is characterized by an absolute white cell count >1000 cells/μL with a lymphocyte fraction >80% and triglyceride level >110 mg/dL. It may also have elevated total protein and albumin levels (less than that of serum), a specific gravity of >1.012, and total fat levels if the infant is milk-fed.[26,27] In the unfed neonate, the fat content of the chylothorax may be quite low, and the fluid does not have the characteristic milky appearance.

Empyema is defined as an exudate purulent effusion with a total leukocyte count >5000/mm^3 and a predominance of polymorphonuclear cells. Hemothorax is characterized by a hematocrit value more than 50% serum hematocrit, but the presence of blood in the fluid is diagnostic in a traumatic hemothorax. Although rare, leakage of TPN though a central line into the pleural cavity has been documented. Analysis of the fluid will show a low leukocyte count and high concentrations of both glucose and potassium. Transudates are effusions with a total protein level <3.0 g/dL or a pleural-to-serum protein ratio <0.5, and a total leukocyte count <1000/mm^3 with predominance of mononuclear cells. Exudate, on the other hand, has a protein level >3.0 g/dL with a pleural-to-serum protein ratio >0.5, pleural fluid LDH values >200 IU/L, or a pleural-to-serum LDH ratio >0.6.

MANAGEMENT

General management principles

Because neonatal pleural effusion is associated with a wide array of disorders and accompanying clinical circumstances, the management of patients with this condition varies considerably. Although there are some case series of neonatal pleural effusion,[3,15,28] clinical outcomes are still poorly understood, and there are no prospective or randomized trials regarding treatment. To date, there has been a lack of protocol regarding treatment approaches for neonatal pleural effusions, although two guidelines for management of pediatric chylothorax have been proposed.[27,29] The timing and type of operative intervention have been particularly controversial. There has been introduction of new medical therapies, but where in the treatment algorithm these medications are useful is yet to be determined.

Despite the differences between the pediatric population and neonatal population, it is generally agreed that the initial treatment should be nonoperative management. The duration of medical therapy can range from days to weeks, and the critical and unresolved issue is the early identification of babies for whom the morbidity of medical therapy will exceed that of early surgical therapy.[19]

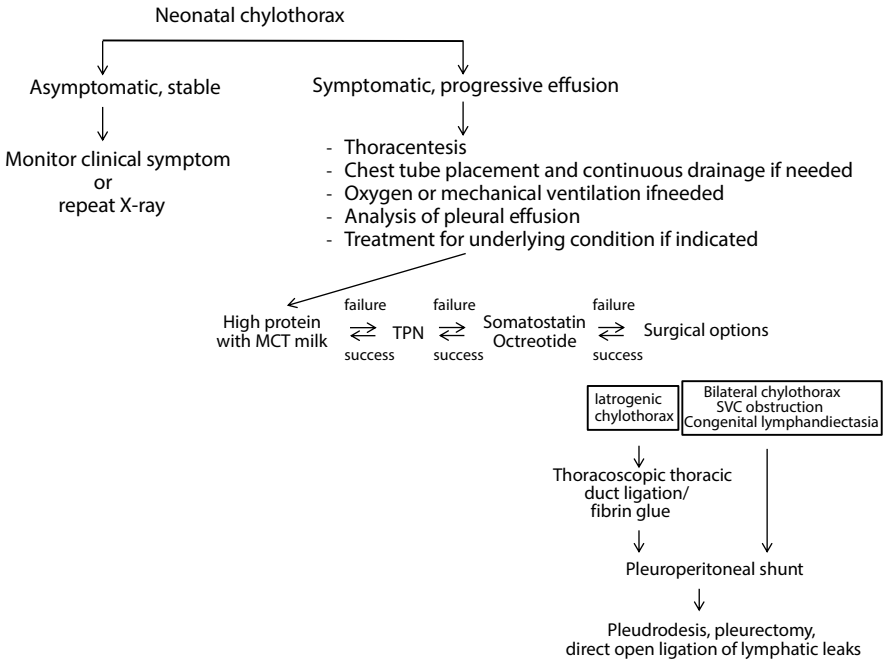

Figure 41.2 Algorithm of management principles for neonatal pleural effusions. MCT: medium-chain triglyceride; SVC: superior vena cava; TPN: total parenteral nutrition.

The main principles of nonoperative management of pleural effusions include the following (Figure 41.2)[29]:

1. Initial drainage and continuous drainage if needed
2. Dietary modification
3. The use of drugs to try and decrease the production of fluid (somatostatin [SST], octreotide [OCT])
4. Pleurodesis using agents such as OK-432 and doxycycline
5. Treatment of underlying cause
6. Supportive care as needed—ventilation, nutrition
7. Prevention and treatment of complications

Nonoperative management

Initial thoracentesis is diagnostic and provides immediate relief of respiratory failure. If the size of the pleural effusion compromises respiration, and/or there is a high likelihood of ongoing fluid production and reaccumulation, a chest tube should be inserted for continuous drainage to keep the lungs fully expanded. Adequate drainage is necessary for sealing chyle leakage. If there is a need for repeating thoracentesis after the initial drainage, a thoracostomy tube is usually placed because of increased risk of producing pneumothorax and introducing infection. Prophylactic antibiotics are given when chest tubes are in place, since many of these neonates have an acquired immune deficiency caused by the acquired lymphocytopenia.

An initial nonoperative management relies on adequate drainage of the effusion in conjunction with nutritional supplementation. Enteral feeding (high protein and fat-free) with medium-chain triglycerides (MCTs) should be given to reduce the flow of chyle through the thoracic duct while waiting for spontaneous healing. MCTs, which have a 6- to 12-carbon backbone, are the only fats to be absorbed directly via the portal system, bypassing the lymphatics. On the contrary, more than 60% of ingested fats travel to the bloodstream via the thoracic duct. Some investigators have observed no difference in MCT or TPN with regard to duration or amount of chylous drainage.[30] In recalcitrant or severe cases, patients may require TPN or a combination of both modalities. When superior vena caval thrombosis is present with chylothorax, the albumin, gamma-globulin, and fibrinogen that are contained in chyle, as well as fat-soluble vitamins, are adequately replaced. The majority of cases of congenital and iatrogenic chylothorax resolve spontaneously with nonoperative management with MCT-enriched diets and/or TPN.

SST and OCT are established but controversial medical treatment alternatives for congenital and iatrogenic chylothorax recalcitrant to nonsurgical therapies. Growing evidence from case studies suggests that SST and OCT exert a positive effect on persistent congenital and postoperative chylothorax.[31] SST is a polypeptide with mainly inhibitory actions on the release of various hormones (e.g., growth hormone and insulin) and lymph fluid excretion. OCT is a synthetic long-acting SST analogue with antisecretory properties similar to those of SST. It is thought that OCT may act directly on SST receptors in the splanchnic circulation to reduce lymph fluid production. OCT also decreases the volume of gastric, pancreatic, and biliary secretions, thus reducing the volume and protein content of fluid within the thoracic duct, because thoracic duct lymphatic flow depends on splanchnic vascular tone as well as gastric motility. Current research suggests that OCT is well tolerated, even with several modes of administration. SST is usually administered as an intravenous infusion (a median dose of 204 μg/kg/day for a median duration of 9.5 days). OCT is administered either as an intravenous infusion (a median dose of 68 μg/kg/day for a median duration of 7 days) or subcutaneously (a median dose of 40 μg/kg/day for a median duration of 17 days).[31] Also, a different way of administration, such as initiation with 0.5 μg/kg/hour of OCT and gradually increasing the dose up to 10–12 μg/kg/hour, was reported.[31,32] Reduction of lymphatic flow rate is usually evident within 3–6 days after initiation of SST or OCT. Use of SST or OCT has been shown to shorten the duration of intensive care treatment, reduce the need for recurrent thoracentesis, and decrease the amount of fluid and plasma infusions, thereby reducing the risk of infection. To date, no randomized controlled trials have been identified; reported route of administration, dose, duration of therapy, and strategy for discontinuation of therapy vary; and the optimal way of administration is not known.[33] Unfortunately, specific pharmacokinetic data are not yet available regarding these agents in neonates and children. Both SST and OCT are considered safe with potential adverse effects, including cholelithiasis, liver impairment, renal impairment, transient glucose intolerance, hypothyroidism, and necrotizing enterocolitis. It is thus prudent for patients to undergo routine monitoring of liver function, blood glucose, and thyroid parameters during the course of treatment.

OK-432 (Picibanil) is a lyophilized incubation mixture of the group A *Streptococcus pyogenes* of human origin for use in pleurodesis. It is presently used to treat fetal chylothorax and congenital cases resistant to SST/OCT as well as adults with chylothorax. To date, information is sparse, and reports emanate primarily from centers in Japan, where OK-432 is manufactured and readily available.

Operative management

Surgical intervention is warranted when nonoperative management fails to significantly diminish lymphatic drainage, or if a patient's respiratory, nutritional, or metabolic status declines (Figure 41.2). There is no consensus on the timing of surgery, but the goal is to intervene prior to development of morbidity. Possible clinical conditions that have a high failure rate with nonoperative management include iatrogenic cases where there is injury to the thoracic duct and massive lymph leakage, vena caval obstruction or elevated central venous pressures, and congenital chylothorax associated with superior vena caval thrombosis in the premature neonate. Although there is no consensus on timing of surgery, many will consider early intervention in the high-risk cases.

The percentage of neonates requiring surgery with failure of nonoperative management and the timing of surgical intervention vary widely among reported series, dependent upon the patient population being studied, etiology, and the clinical status of the patients. There are several surgical approaches, and different options are often used in combination. They include thoracic duct ligation (open thoracotomy or thoracoscopy), pleurodesis (mechanical and chemical), pleurectomy, and pleuroperitoneal shunting.

THORACIC DUCT LIGATION

Direct surgical ligation of the thoracic duct is historically the most common surgical therapy and has been the most definitive and successful in resolving chylous leak if the site of rupture can be identified intraoperatively. It can be performed via an open thoracotomy or a thoracoscopic approach. Video-assisted thoracoscopic procedures are being used with increasing frequency. These procedures offer the advantage of access to the entire hemithorax, with excellent visualization of the mediastinal structures. This approach allows application of clips to the thoracic duct at the hiatus or to the thoracic duct at the level of the injury or pleural defects. It also facilitates mechanical or chemical pleurodesis and application of fibrin glue. Despite its advantages, its use is limited by an infant's size and pulmonary status. Also, it may be difficult to correctly visualize leaks in the presence of a massive chylous effusion. The thoracoscopic approach has been shown to have a lower rate of complications.[34,35]

Regardless of the surgical approach, visualization of the site of chyle leakage can be difficult. Giving cream or milk through the nasogastric tube several hours before the operation or injection of 1% Evans blue dye in the thigh helps to identify the sites of leakage by giving the lymphatic drainage a color. Major leaks from the thoracic ducts can be closed by direct suturing or by ligating the duct above and below the leak. If the thoracic duct or site of the leak is not identified, a mass ligation of the thoracic duct and its surrounding tissue can be done between the aorta, azygos vein, and esophagus, adjacent to the vertebral body.

PLEURODESIS AND PARIETAL PLEURECTOMY

Pleurodesis and parietal pleurectomy, which obliterate the pleural space, have been used when there is generalized weeping of chyle from parietal pleura. Mechanical pleurodesis is commonly performed with thoracoscopy with direct irritation of the parietal pleura. Chemical pleurodesis, with the administration of a sclerosing agent (tetracycline, talc, povidone–iodine, OK-432) is performed via a chest tube. Parietal pleurectomy has been reported as a successful option for the pediatric population in 1980s, but it is rarely performed now. It is an extensive surgical procedure that may increase the possibility of pulmonary lymphedema, fibrosis, and further pulmonary compromise.

Fibrin glue applied to the leakage site after patent ductus arteriosus ligation has been reported to successfully manage chylothorax in both a 3.5-month-old infant and a premature infant weighing 600 g.[36]

PLEUROPERITONEAL SHUNTS

Pleuroperitoneal shunts, first used by Azizkhan et al.[37] in 1983 to treat five ventilator-dependent infants with persistent chylothorax, are used as a surgical treatment option. The procedure avoids the risks associated with a more complicated open surgical procedure in high-risk infants and is considered safe, highly effective, and easy to perform. Pleuroperitoneal shunts provide a way of draining chyle from the pleural space to the peritoneal space but require manual compression of the shunt chamber.[37] During the immediate postoperative period, the pumping chamber is compressed 50–100 times per hour in order to completely clear the hemithorax of chyle. As the infant's clinical status improves, a gradual decrease in the frequency of shunt compression is begun. Resolution of pleural effusion often occurs within 2–3 weeks. The valve and pumping chamber sometimes become dysfunctional after several weeks due to an accumulation of fibrin and protein in the valve mechanism. Because it is less invasive, it is ideal for patients who require a relatively short or stabilizing procedure. Also, in case of both pleural effusion and intra-abdominal ascites, a combination of a pleuroperitoneal shunt and a peritoneovenous shunt may be required.

OUTCOME

In general, neonatal pleural effusion has a good prognosis, except in hydropic neonates. The mortality rate in hydrops is 53%. It has been reported that hydrops resulting from lymphatic dysplasia has a more favorable outcome. However, the causes of death were related to the underlying disease, such as respiratory failure due to pulmonary hypoplasia, multiorgan failure, or sepsis, and not to the pleural effusion. Neonates with acquired iatrogenic pleural effusion tend to have increasing needs for parenteral feeding, oxygen therapy, and diuretic regimen, as well as longer periods of mechanical ventilation and a longer stay in the neonatal intensive care unit (NICU), when compared to congenital primary pleural effusion. Recently, blood albumin level has been proposed to be predictive of prognosis for neonatal pleural effusion.[15]
